Foreword

The selection of method may have a crucial impact on the results. The volume of the non-market services in the Danish National Accounts is measured by equating them to the volume of inputs used to produce these services. Internationally as well as nationally, this input-method is not considered to be the optimal measure, since it does not reflect all the real value of the volume growth and the productivity as well as the quality changes of these services.

Recent years' growing interest in the non-market output has resulted in increased interest in finding optimal methods to measure the output of non-market in the economy and therefore, the European Commission passed a Resolution changing the international guidelines for calculating national accounts using constant prices, i.e. adjusted for price changes in December 2002.¹

The new guidelines result in radical changes of the method for calculating the production value of the individual services within the public sector. The new method suggested by the Commission is based on a count of the actual output produced.

This publication, *General Government Output and Productivity* covers the non-market individual services provided by the government and forms the basis for complying with the Commission Resolution and highlights the effects of the new output-based method on the Danish National Accounts. The new method makes it also possible to compile the productivity figures for the non-market public sector.

This publication is the third of a number of planned publications reporting the results of the development of the output-based measures for General Government. The work was performed by Statistics Denmark in collaboration with the Danish Ministry of Finance.

The publication was produced by Statistics Denmark's Division for National Accounts by Head of Section Nura Nursen Deveci.

EXECUTIVE SUMMARY

Overview

Background One of the crucial objectives of the National Accounts is to evaluate the volume growth in every sector of the economy as a whole. The production of the general government in Denmark makes up about 25 per cent of the whole economy, and it is therefore essential that it is measured in a correct way, reflecting the real volume growth.

In Denmark the government-provided non-market service measures are based on the inputs used to produce these services, instead of the actual outputs produced, and the real market value is not reflected by this input-method. A direct consequence of the current input-based procedure is that part of productivity changes for government-provided services are ignored, because outputs are assumed to follow the same pattern as inputs. Therefore, it is essential to find more accurate measures of the volume growth of public services in the National Accounts in accordance with the resolution passed by the European Commission in December 2002. The resolution laid down the new international guidelines for calculating national accounts, using constant prices, i.e. adjusted for price changes.

Output-based method The output-based method involves a radical change in the way calculations, using constant prices should be performed for these services in the future; the current input-based method rests on a close correlation between costs and production (the total cost measured at constant prices sums up to the production value), while the output-based method involves calculating the production value, using constant prices based on counting the number of representative activities in different categories and then weighting them together, using the unit cost for each activity.

The results in this publication show the extent to which the new guidelines for calculating consumption expenditure of General Government, using constant prices, affect the national account figures. The publication highlights the consequences for key figures, such as production value, gross domestic product (GDP) and labour productivity, as well as describing the measures of the quality of health care and educational services.

Input- and output-based measures of non-market output in National Accounts

The volume of health care, social protection and educational services is calculated according to the EU guidelines. The results show that changing the compilation method will result in substantial revisions to the Danish national accounts figures. In this publication, figures for 2000 to 2008 are compiled.

Effects on price indices Figure A shows that output-based prices for the whole non-market services were increasing less rapidly than input-based prices, which implies that real growth of the non-market economy has been underestimated. Notice that the differences between the two indices are increasing over time.

Figure A Price indices for the whole non-market economy

NB: National accounts figures for 2008 are not final.

Effects on production value

The overall production value increases by between DKK 2 and 16 billion annually as a result of the output-based method. The health care services contribute positively over the entire period, when the new method is applied (figure B). Social protection services contribute negatively in all periods, indicating that the production value of social protection is overstated when using the input-based method. The output-based method has a generally positive effect on educational production value, which contributes positively in four out of six years. The effects of the new method on recreation and culture are changing over time, but since this sector represents a very small part of total non-market services, it has minor impacts on overall production value.

Figure B Difference in production values distributed according to service type. Chained 2000 values

NB: National accounts figures for 2008 are not final.

Figures for Social protection for 2007 and 2008 are not included.

Effects of the output method on the whole economy

Changes in GDP The output-based constant price calculation changes the growth rate, of GDP figures. In 2004 (the year with the greatest difference), the volume growth would be 2.7 percentage point, whereas the official growth rate is 2.3 percentage point. In 2001 and 2006 the difference is 0.3 percentage point, while in 2003 and 2005, a minor decrease in GDP growth of 0.1 percentage point was observed. In 2007 the differences between the two methods are minor (the output-based GDP is 0.1 percentage point higher), while in 2008 both methods generate negative GDP growth rates of -0.9 and -0.6 per cent for input- and output-based methods, respectively.

Figure C Growth in gross domestic product distributed according to calculation method

NB: National accounts figures for 2008 are not final.

Productivity increases If the alternative figures are used for the production value in productivity calculations, an equivalent effect is observed (figure D). Productivity is here measured as output per hour worked for the total economy. If productivity figures published by Statistics Denmark are compared with output-based calculations, productivity generally increases more, using the alternative output-based figures. The most visible difference occurs in 2004, where the output-based method produces a productivity increase, which is 0.5 percentage point higher than the official calculations. For the period as a whole, the increase in productivity is 0.4 per cent annually, while the alternative calculations produce an average annual increase of 0.5 percentage point. These calculations show that the average productivity growth for 2000-2008 would be 0.1 per cent higher using the output-based calculations. The productivity decreased sharply in 2008 using both methods.

Figure D Output per hours worked distributed according to calculation method

NB: National accounts figures for 2008 are not final. For interpretation of current data, see fact box: Facts about non-market-related finance and work productivity.

No significant quality effects

The quality adjustment of health care and education has positive but insignificant effects on the production volume growth, compared to the output-based method without quality adjustment. It was very difficult to define and prepare the quality indicators, and therefore it was only possible to prepare them for a few areas. Since only a small part of the non-market production is quality adjusted, the effects are not fully reflected. The quality indicators are only calculated for the first six years.

Key figures are affected

The results demonstrate that if these calculations, which are based on the new European guidelines, are implemented, this will result in substantial revisions to several of the key figures in the national accounts.

1. Introduction

New method in the National Accounts In December 2002, the European Commission passed a resolution changing the international guidelines for calculating national accounts, using constant prices, i.e. adjusted for price changes². One of these changes concerns the calculation of the production value for the individual services of General Government.

Background In Denmark the government-provided non-market service measures are based on the inputs used to produce these services, instead of the outputs produced, i.e., setting input equal to output and the real market value is not reflected by this input-based method. The input-based method neglects changes in productivity and has a tendency to under-/overestimate the contribution of the government output to the growth rate of GDP. The government output in Denmark accounts for a very large fraction of the entire economy (about 25 per cent), and it is therefore important that output is measured correctly.

The Commission resolution The resolution implies radical changes in how calculations using constant prices should be performed in the future for the non-market individual services. While the current input-based-method rests on a close correlation between costs and production (total costs using constant prices produce the production value), the new output-based method involves calculating the production value, using constant prices based on the production value for the prices of the year and on information about the volume growth for the actual product. The output-based method also includes explicit quality correction of the government services.

The purpose of this publication is firstly to calculate the production value for non-market services using constant prices based on the new guidelines, partly to compare these figures with existing ones; and finally, to evaluate the quality of the calculated data.

This publication is based on two pilot projects published in 2007 and 2009, and contains updates of figures and a presentation of the progress made since then. Furthermore, the calculations are extended to include Recreation, culture and religion; areas within non-market public services that were not covered in the last issues of the publication. This publication also covers the initial experiments with explicit quality adjustment for health care services as well as some educational services and includes some discussion about the quality of social services.

Data inconsistency due to local government reforms In Denmark, a major reform in the local governments was implemented in 2007. The reform implied substantial changes in the way that most services were compiled. This data break must be taken into account when comparing 2006 with 2007 in this publication. Moreover, due to problems with data inconsistency we have chosen not to publish data for social protection services for 2007 and 2008 yet. We will be working on creating consistent time series on social protection services and expect to publish such series in the autumn 2011.

2. Methods in general and discussion of the quality issue

One of the most important objectives of the National Accounts is to value the production in every sector of the economy as a whole. Production is the transformation of inputs, such as labour and capital, into output in the form of goods and services, which are delivered to other units. For example, a pupil in a school is consuming the production of education services.

Government output The aim of this chapter is to describe the method applied to measure the government output in Denmark. The government output is generally non-market since it is

² Commission resolution of 17 December 2002. Official Journal of the European Union 20.12.2002

supplied free of charge or at economically insignificant prices. The price is not economically significant if it covers less than half of the costs of the service. The lack of economically significant prices for non-market services implies that it is not possible to value the output of non-market producers in the same way as the output of the market producers. Hence, the value of output of non-market producers in the National Accounts is valued by summing total production costs.

*Individual
and
collective services*

The non-market services are divided into individual and collective services. The individual services are consumed by the household, while the collective services are provided to society as a whole.

*Individual
services*

In Denmark, education, health and social services are the most common kinds of government provision free of charge or at prices, which are economically insignificant. The above mentioned individual services – including recreation, culture and religion – comprise 73 per cent of non-market output. Under these circumstances, the price paid cannot be the basis for valuing it (as would be the case with market goods and services). Its valuation for the National Accounts is the sum of the costs incurred in production. That is the sum of the intermediate consumption (the goods and services used in producing the service), compensation of employees (costs of doctors, nurses, teachers, etc.), consumption of fixed capital (depreciation of medical equipment and hospital and school buildings), and other taxes and subsidies on production.

Figure 2.1 General government expenditure on non-market individual services. 2007

The breakdown of the 2007 costs of providing individual series is given in figure 2.1. Social protection has the largest weight with 34 percent of the total individual consumption followed by health care and education that make up 31 and 29 percent respectively. Recreation, culture and religion make up 6 percent.

Education, health care and social protection services are the production of the education, health and social protection industries, whether provided on a market or a non-market basis. Producers purchase intermediate inputs (goods and services) from other industries; they employ human resources and they use capital to transform these inputs into services which are then delivered to final consumers, such as pupils, patients or residents in a home for elderly people. The incomes generated in this transformation are the value added of these industries and their contribution to GDP.

*Services
at market condition*

The individual services, e.g. medical practice, which are purchased by the government from market producers, are called market services, because the services are sold at economically significant prices, i.e. the prices and quantities determine the value at which the producers supply and the purchasers buy. These services are not discussed in this publication.

<i>GDP and productivity</i>	Setting input = output has a tendency to underestimate the contribution of the government output to GDP. It also neglects changes in public sector productivity.
<i>Deflating methods</i>	<p>Since the point of interest is GDP growth at constant prices and the productivity figures, the focus is on government output, which implies that it is necessary to apply a method to deflate expenditures on non-market production in order to measure the output growth of the public services and the productivity, either for individual units or across an industry.</p> <p>The internationally increasing interest in finding a method for replacement of the approach of equating input to output has inspired researchers to find a method, providing a better measure of the government activities and the productivity.</p> <p>Including Atkinson's Review (2005), many researchers have suggested a method of directly measuring the volume of government output. The new output measure depends on aggregating a set of volume measures for different types of activities, multiplied by a set of unit costs. The volume measure provides an indicator of the growth rate of the economy and makes it possible to measure the productivity of the government output. Volume is regarded as having dimensions of quantity and quality.</p>
<i>Identification of public production</i>	Identifying the production value of the public services is very complex. The main questions to be answered are: what is the public output and how do we measure it? However, identifying such indicators is not that simple. It requires distinguishing between output, outcome and activity. Outcome and activity is influenced by the recipients of the public services, for instance the result of a treatment at hospital is influenced both by the health care authorities through drugs etc. and, also, by the individual, e.g. by lifestyle changes etc. In this publication we will identify relevant quality and quantity indicators for measuring volume of government output.
<i>Quantity</i>	In order to calculate the public output in the new way, a cost-weighted price index is used to replace the input-based measures. A cost-weighted activity index is based on output-indicators (for instance, hospital admissions, outpatients, number of students etc.) and their unit costs. Indices of the number of output-indicators measured in each category are then weighted together, using the cost-share for each activity so the total of output growth can be calculated.
<i>Quality</i>	To be able to reflect the changes in the real value of output, it is important that the calculation of production value takes quality changes into account. Atkinson's Review (2005), Principle B proposes that the public production value has to be measured in a way adjusting for quality changes. When the quality changes are not taken into consideration the economic growth will either be under- or overestimated.
<i>Market vs. non-market production</i>	In the market sector, production is normally constructed from the quantity of different types of goods/service and their prices, where the prices reflect the value of a given product (the market mechanisms are assumed to ensure that the values are reflected in the prices). Quality is an important part of the products, since, e.g. basic products and luxury goods are priced according to their quality. When one considers the changes in price and volume of the market production, it is also necessary to look at the changes in the quality. The same is true for the non-market-production, but here it is difficult to measure the quality, as the final prices on production are absent. Since the prices of the non-market sectors production are missing, the unit costs are used to weight different production values.
<i>Quantity vs. quality</i>	Given that the changes in volume output consist of quantity and quality, where the quantity is defined as the number of units and the quality is defined as the characteristic of different products, both the changes of quantity and quality have to be taken into consideration in order to measure the correct volume changes in a given product. If the quality changes are not taken into consideration, some of the changes in the measured volume will be missing. Only in the case of completely homogeneous

products (e.g. rice and oil, which do not change characteristic over time) the volume can be calculated based on the quantities alone, i.e. the number of units in the current period multiplied by unit costs in the basic period. Since most public services are heterogeneous and change over time, it is necessary to quality adjust the non-market individual services in order to reflect all changes in the products.

Aspects of quality The valuation of a product will depend on different aspects of quality, and two aspects that will be treated in this project are:

- The extent to which the non-market service succeed in delivering the intended outcome
- The extent to which the service corresponds to users' requests.

This publication will discuss and present some examples of quality indicators in health care service and education, and discuss the quality of social protection services. Also, the above-mentioned aspects will be further developed for each of these services.

Outcome vs. output It is important to recognise the difference between measuring output from the public service and measuring outcomes, and the link between them. Measuring quality of the public individual personal services in an optimal way is not easy, given that the individuals receiving the services are themselves both input and output in the process, and they also sometimes take an active part in the process. For instance, measuring the direct outcome of educational services will depend, besides the delivered education service, on several other factors, such as the pupils' ability to learn, socioeconomic background and motivation. Measuring the direct outcome of an education service can be examining the pupils' level of knowledge at the beginning of the school year and the same examination could be conducted at the end of the school year. Hence the level of transferred knowledge and skills are measured (keeping the background factors constant, assuming that abilities and socioeconomic background will not change during the school year. The only factor that may vary is the motivation and effort from the pupils' side).

The same measurement problem exists for health care services - how can the contribution of health services be measured? The most optimal way may be to measure the patients' health status before and after a given treatment, keeping everything else constant (lifestyle, age etc.).

But such measures require a vast amount of resources and efforts and the challenge is how to measure the outcomes of the different services contribute to the output?

Identification of quality dimensions Quality consists of different dimensions, and it is necessary to define the relevant quality dimensions within each area and decide how they should be weighted. Weights need to be determined in order to combine the different aspects to form a single quality adjusting indicator. For complex areas, e.g. health care, the quality consists of many dimensions, for instance the effectiveness of the treatment, waiting time before a given treatment etc. An important challenge is to combine the different quality dimensions and weight them according to importance.

However, measurement of quality is a complex task and is based on subjective assessments and choices, such as:

- Choice of quality indicator(s)
- Scaling problem, i.e. how does changes in the quality indicators affect the level of quality?
- Choice of how to weight different indicator

The non-market output adjusted for quality is given by;

$$\text{Output} = \text{Quantity} \times \text{Quality}$$

The characteristic of the quality indicators

Quality indicators have to reflect all changes in the public sector output, i.e. they should reflect whether the marginal contributions from the public services are positive or negative. In addition, the indicator set should be based on three main considerations: the importance of the indicator, the scientific and methodical reliability and the access to data.

2.1 Productivity

Input-based productivity

One of the weaknesses of the input-based method is that it ignores productivity changes for the government output. It assumes that the composition of the workforce and capital is identical and that any calculation of the productivity for the non-market economy between two periods will by definition be close to zero. This is due to the causality between the concepts: number of working hours, salary, and gross value added. The close relationship between these is illustrated in the fact box below and shows why there are no changes in input-based productivity.

In practice, the composition of the workforce and capital will not be constant over time, since there are constant changes to the workforce volume and its educational composition changes, along with investment in new capital equipment. Productivity will therefore, change over time.

Output-based productivity

This situation does not apply if the production value, and thereby the gross value added, is calculated according to the output-based method. When this method is applied, the link between the cost of wages and the production value is broken.

The production value can now change, regardless of the amount number of working hours.

Facts about non-market-related finance and productivity

Example of the impact of an increase in employment in the non-market economy when calculating the national accounts.

Stage 1:

New employee, involving more working hours and an increase in the cost of wages.

$$\text{Employment} \uparrow \Rightarrow \text{Hours} \uparrow \Rightarrow \text{Wages} \uparrow$$

Stage 2:

The cost of wages rises. The production value increases by an equivalent amount, since the cost of wages is included directly in the calculation. The gross value added increases by an equivalent amount.

$$\text{Wages} \uparrow \Rightarrow \text{Production value} \uparrow \Rightarrow \text{Grossvalueadded} \uparrow$$

Stage 3:

Work productivity, which is defined as the gross value added per hour, is unchanged, since the changes to the gross value added and the hours are the same.

$$\text{Workproductivity} \Leftrightarrow \frac{\text{Grossvalueadded} \uparrow}{\text{Hours} \uparrow}$$

Or

If the number of hours is unchanged, every thing else being equal, the gross value added will also remain unchanged, and work productivity will by definition remain unchanged.

3. Individual non-market services in the National Accounts

This chapter will describe the public non-market individual services in the National Accounts. Furthermore, methods applied to calculate non-market services in the National Accounts at constant prices will be described in detail.

In Denmark, the national accounts are compiled on the basis of an analysis and a reconciliation of statistical data for the economy as a whole in what is known as a product balancing system; i.e. all data is classified according to the national accounting products to which the individual statistical data refers. The most detailed, harmonised data is found in the product- and sector-distributed supply-use matrix for the individual year, abbreviated SUT.

At Statistics Denmark, the accounts of General Government (GG) are included in a joint system, known as the Database of Integrated Public Accounts. Data is distributed and processed in two parts: data for public, non-market activity (OIMA) and social services in kind.

Private activity in the health sector is covered in the national accounts by drawing on two sources of accounting statistics: Statistics Denmark's general accounting statistics for private commerce and the more concise, tax-based accounting statistics (SLSE).

Finally, Statistics Denmark's consumer survey is included in establishing the measurements for household consumption of (health-related) products. The national accounts draw upon all these statistics in a more detailed format than that in which they are made public.

3.1 Public production

Delimiting a financial unit upon which the national accounts are based is straightforward for many public institutions, but it can be difficult for some institutions. There are two types of levels in delimiting a unit: both the institutional unit, corresponding to the independent, financial decision-making unit, which may enter into binding legal contracts, and the local technical unit, also known as the workplace, where production (or consumption) takes place.

The concepts of market and non-market play a central role in this feature publication. They are linked both to the institution and to the activities of these institutions distributed according to workplace. We thus speak of a (non-)market activity and a (non-)market unit. The definition of the latter follows:

Definition of non-market unit

In the national accounts, "non-market" units refer to those whose sales income represents less than 50 per cent of the production costs.³

Since public units have, in many cases, their own income, which cannot be considered as tax, but as user payment or actual sales income, these are also relevant. Sales income in non-market units is logged under a separate product number. They are classified as market production in a workplace under the non-market unit.

Definition of the production value for non-market units

Public non-market production is by convention calculated as the sum of the following production costs (ESA 95, chapter 3.53):

- intermediate consumption
- consumption of fixed capital goods
- wages, salaries and employer's contributions
- other production taxes and subsidies

³ See the manual documentation in the central Eurostat publication, "The European System of Accounts: ESA 95" (abbreviated ESA 95) chapters 3.17-3.45 for a detailed description of the classification of public and related units.

When recording non-market production in a public, non-market unit, which also has sales income, the unit's overall production is calculated according to the above convention, after which this is divided into two parts. One part is paid by the users and the other, under public consumption, is paid by the public. The amounts obtained are entered under the relevant product number.

The value of the consumption of General Government can be determined from the public non-market unit production by deducting all sales income, deducting the value of software manufactured for internal use and adding social services in kind.

3.2 National accounting products

The Danish national accounts are based on a system of approximately 2,350 detailed product balances. Each product is linked to a unique national accounting product number code. In the national accounts, data supplied by the Office of Public Finance is classified according to product number.

This section provides a brief outline of the way in which public non-market activity using constant prices is calculated in the national accounts. This description is based on documentation of the calculation of the national accounts in *Inventory of Sources and Methods: Price and Volume Measures in the Danish National Accounts*, Statistics Denmark 2002

The public non-market activity is recorded at current prices in the Danish national accounts by adding the associated costs, i.e. the input to the non-market sector consisting of:

- Compensation of employees
- Intermediate consumption
- Consumption of fixed capital goods
- Other taxes and subsidies on net production

Conversion to constant prices is performed in a similar manner, in that the individual cost elements are deflated separately. In other words, inputs are deflated. The deflation method for each of the four cost elements is explained below.

3.2.1 Compensation of employees

When determining the cost of wages for an activity, the calculation should ideally include all the employer's costs that are associated with the appointment of employees. In other words, the calculations should include not only the salary paid to the employee, but also other employer's costs such as the employer's pension and social protection contributions.

The wage index used to deflate of compensation of employees should consequently cover the same concepts.

In the context of the national accounts, a rise in the average cost of wages is not deemed to necessary represent a wage increase. We distinguish between changes in remuneration that are due to a change in the quality of the workforce and changes that occur to ensure the availability of a sufficient workforce volume and quality.

This, which in the context of the national accounts should ideally be described in the wage index, is exclusively the amount by which the average cost of wages has increased to ensure availability of a continuous workforce volume and quality (the price component).

Based on this principle, it is relatively clear that general wage increases, collectively agreed and implemented, including e.g. the Danish Regulation Order, should result in increases in the wage index. This also means that changes, e.g. to working hours without a decrease or increase in wages, should result in a change in the wage index.

Overtime often involves extraordinary remuneration. Changes in the average wage arising from this extraordinary remuneration should result in changes in the wage index. On the other hand, for the purpose of the national accounts, changes in the average wage arising as a consequence of changes in the age and functional composition of the workforce in regard to classifications, should not result in changes in the wage index. These reflect changes in the quality of the workforce and should therefore be expressed in a change in the volume of the public non-market activity (the volume component).

3.2.2 Intermediate consumption

Intermediate consumption in production in public service and management are deflated using a sector-specific price index.

Sectors involve both public and private activities, and it is assumed that for intermediate consumption in production, the price growth in the public part of the relevant sectors follows the price growth in the relevant sectors as a whole.

Implicit price indices for the purchase of products in the respective sectors are therefore calculated on the basis of the product balances, and these are used to deflate intermediate consumption in General Government.

3.2.3 Consumption of fixed capital goods

Consumption of fixed capital refers to the physical and financial deterioration of capital equipment, i.e. machinery, vehicles, constructions and so on, during production. Capital equipment is an integral part of the national accounts, and provides the source of the price index for deflation.

3.2.4 Other production taxes and subsidies net

At constant prices, other taxes and subsidies on production should ideally grow in line with volume growth for the products that are subject to taxation/subsidisation.

The production taxes that have the greatest effect on public service and management are property/land tax and vehicle tax. It is generally assumed that this stock remain unchanged over time. In other words, taxes on the other production distributed by sector are kept stable in relation to the base year. Subsidies are deflated by wage index.

3.3 Output-based constant price calculations

For a number of years, questions have been raised about the method by which the national accounts figures for the non-market economy are calculated at constant prices. This is a national, and particularly an international, phenomenon. In almost every country, national accounts figures for the non-market economy are used intensively by politicians, the press, analysts, and others. Recent years have seen increasing interest in these calculations. The growing use of these figures has also resulted in increased interest in the method by which the calculations are performed.

Due to the lack of usefulness of figures calculated according to the input method for productivity analyses, new guidelines as to how such calculations should be performed have been prepared. The European Commission Resolution of December 2002 changed the international guidelines for calculating national accounts using constant prices, so that only deflators describing price or volume growth from the output are approved from 2006 onwards⁴.

Denmark expressed concern about the short notice provided for such a radical change in calculation principles, and therefore Denmark requested to be exempted, and was consequently granted an exception to this calculation method until 2012. The calculations in this publication meet the new European requirements, but will not be implemented in the official accounts figures. This ensures that the time frame for implementing the method is long enough to ensure a sufficiently high quality data for the whole period.

The next few sections describe the guidelines for output-based figures. We begin with a general description. This is followed by a chapter examining the way in which health-related calculations should be performed. In chapter 5 we describe the way social protection calculation should be carried out, while chapter 6 describes the guidelines that apply to the educational sector.

3.4 General information about methods used for constant price calculations

Methods that can be used to measure prices and volumes are classified into three groups according to their suitability. The most suitable are classified as A methods, the next best as B methods and the least suitable as C methods.

Methods classified as A and B methods are considered to be of a quality good enough to be approved, while C methods are not of the quality necessary for approval.

Classification of methods

- A methods: The most suitable methods are internationally approved.
- B methods: Methods of poorer quality which are still internationally approved.
- C methods: Methods of a quality so poor that the guidelines advise against using them. C methods are not internationally approved.

In order to meet the requirements in the 2002 Commission Resolution, either A or B methods must be used.

⁴ Commission Resolution of 17 December 2002. Official Journal of the European Union 20.12.2002

3.5 Theory of output-based constant price calculation

This chapter describes how price and volume growth is calculated from a theoretical point of view using the output-based method, cf. the box below.

The difference between input and output deflation

Calculation using constant prices via the input-based method:

Production value using constant prices =
 Intermediate consumption in production using constant prices
 + Consumption of fixed capital goods using constant prices
 + Wages, salaries and employer's contributions using constant prices
 + Other production taxes and subsidies using constant prices

In other words, a separate price index is NOT used for the production value.

Calculation using constant prices via the output-based method:

Production value using constant prices = Production value at current prices/the relevant price index

In other words, the production value using constant prices is calculated WITHOUT regard to the costs at constant prices.

The aim is that the output-based method should be analogous to the method used for the market economy. In order to be able to do this, information regarding prices and volumes in two consecutive periods is required.

The calculation of the value for the period t can be expressed as the multiplication of the prices, P , and volumes, M , for the period. This gives us the value V_t^Y for j products:

$$V_t^Y = \sum_j P_{t,j} * M_{t,j} \quad 3.1$$

To calculate chained values we need to know the volume in the period t measured at the period $t-1$ prices. The value listed in the prices for the previous year, V_t^D , is calculated as the volume in the period t multiplied by the prices in the period $t-1$ for j products:

$$V_t^D = \sum_j P_{t-1,j} * M_{t,j} \quad 3.2$$

Subsequently, bilateral Laspeyres volume indices, $I_{t-1,t}^B$, between periods $t-1$ and t , can be calculated as:

$$I_{t-1,t}^B = \frac{\sum_j P_{t-1,j} * M_{t,j}}{\sum_j P_{t-1,j} * M_{t-1,j}} \quad 3.3$$

When calculating chained volumes, a specific year should be used as a reference, i.e. the prices for the year and constant prices should be identical. If period t is chosen as the base year, the equation for the Laspeyres chain index between periods t and $t+1$ will be as follows:

$$V_{t,t+1}^K = \frac{\sum_j P_{t,j} * M_{t+1,j}}{\sum_j P_{t,j} * M_{t,j}} \quad 3.4$$

while the formula for the following year is:

$$V_{t+1,t+2}^K = \frac{\sum_j P_{t+1,j} * M_{t+2,j}}{\sum_j P_{t+1,j} * M_{t+1,j}} * V_{t,t+1}^K \quad 3.5$$

3.6 Output-based national accounting calculations

*Adjustment of
national accounts supply-
use matrices*

The output-based method is used in the national accounts in the same way as that used for the market economy. We will now explain how the new calculations can be incorporated into the detailed series in the national accounts, known as SUT.

Price and volume data exists for j , non-market services which cover a specific area, such as hospitals. Data that can be compared between two periods is used in calculations. It is assumed that i treatment types are comparable between two periods. For these i treatment types, the value, V , can be calculated in prices for this year and the previous one according to equations 3.1 and 3.2:

$$V_{t+1}^Y = \sum_i P_{t+1,i} * M_{t+1,i} \quad 3.6$$

$$V_{t+1}^D = \sum_i P_{t,i} * M_{t+1,i} \quad 3.7$$

We can use the above to calculate an implicit price index for the i treatment types:

$$P_{t,t+1}^B = \frac{\sum_i P_{t+1,i} * M_{t+1,i}}{\sum_i P_{t,i} * M_{t+1,i}} \quad 3.8$$

It is assumed that the price growth for i treatment types is representative of all treatment types j . The price index can now be used to deflate the relevant part of production value (PV) in the national accounts incorporating the prices for the year.

Expressed as a formula, this appears as follows:

$$PV_{t+1}^D = \frac{1}{P_{t,t+1}^B} * PV_{t+1}^Y \quad 3.9$$

This produces PV_{t+1}^D , which is the PV for the period $t+1$ calculated at the prices for the previous year, i.e. t prices. PV's for the national accounts can now be chained to a

Laspeyres chain index. To calculate this we use PV_{t+1}^D and PV_t^Y , which is the PV in the prices in the previous period, t . These two PV's are calculated using the same prices for period t , and the difference between them indicates the volume growth between periods t and $t+1$. The volume growth is then multiplied by the value for the previous period in chained prices. For the period immediately after the reference year, the following applies:

$$PV_{t+1}^K = \frac{PV_{t+1}^D}{PV_t^Y} \quad 3.10$$

This is because during period t , the reference year is by definition $PV_t^K = PV_t^Y$, while the following period is:

$$PV_{t+2}^K = \frac{PV_{t+2}^D}{PV_{t+1}^Y} * PV_{t,t+1}^K \quad 3.11$$

3.6.1 Output-based price index with quality adjustment

Multiplying equation 3.8 with a function of quality produce a quality adjusted output-based price index.

$$P_{t,t+1,i}^B = \frac{\sum_i P_{t+1,i} * M_{t+1,i} * F(q_{t+1,i})}{\sum_i P_{t,i} * M_{t+1,i} * F(q_{t,i})} \quad 3.12$$

F is of function of quality, and quality is supposed to consist by different indicators, which are selected and weighted according to their importance (subjective assessment).

4. Health Care

This chapter provides the method of output-based measure of the volume of health care services and goods in the economy to be used for national accounting purposes.

Danish Healthcare Services The Public Danish Healthcare Services are extremely extensive; therefore they are divided into various subsidiary areas. In this context, the relevant areas are:

- Hospital activity
- Treatment by dentists
- Social provisions with and without institutional care

In practice, this division means that individual indices are calculated for:

- General hospital activity
- Public dental services
- Residential and day care places for the elderly

General hospital activity In the case of patients admitted to general hospitals, deflation using fully quality-adjusted indicators based on the classification of Diagnosis Related Groups (DRG) is counted as an A method. If only changes in the composition of treatment within DRG are covered, and the direct/explicit quality correction is omitted, this is a B method. Use of incomplete production indicators, such as the number of patient prescriptions only, is considered to be a C method.

Change in DRG The National Board of Health made some changes in the DRG's between 2006 and 2007 which means that some diseases are difficult to compare over time. This causes some inconsistency in data.

Psychiatric hospitals Until 2006 the specialized hospitals, i.e. psychiatric hospitals, were separate, independent units in the National accounting, but after the local government reforms they are now perceived as being part of general hospitals. At the moment, it is not possible to calculate a separate price index for psychiatric hospitals, but The National Board of Health made a DRG for psychological diseases from 2008. We expect to include these treatments in our calculations, when we have data that is consistent and comparable over time.

Public dental services Methods relating to public dental care treatment are named as the quality-adjusted number of treatments distributed according to type of treatment. If the production indicator is not quality-adjusted, the method is classified as a B method. If the number of treatments cannot be distributed according to type, the requirements for a B method are not met; this is classified as a C method.

Residential and day care places for the elderly Regarding residential and day care facilities for the elderly, it is classified as an A method when the number of people receiving care is distributed according to the level of care. If the total number of people receiving care is used but not distributed according to level of care, this is classified as a B method. In cases where there is no quality adjustment, this is also classified as a B method.

4.1 Non-market production of health care in the National Accounts

Non-market production of health is produced in three sectors, namely:

- 851100 Hospitals
- 851209 Doctors, dentists, veterinarians
- 853209 Social institutions for adults

Hospitals Non-market production from hospital services is placed in sector 851100 Hospitals. Production in this sector is almost exclusively non-market: nearly the entire production value is generated from non-market producers; a minor share is produced by market producers; in this case private hospital. In 2007, the sector's total production value was over DKK 70 billion.

851100 Hospitals

- The production value in 2007 was approx. DKK 70 billion measured at current prices
- 99 per cent of production is non-market
- Hospital services make up 40 per cent of all health services
- Non-market production from hospital services makes up almost 15 per cent of the total non-market production.

Doctors, dentists and veterinarians In sector 851209 Doctors, dentists, veterinarians, production mainly consists of market production. Less than a quarter of the total production value is generated by non-market producers. The non-market production is primarily derived from dental treatment and is associated with public dental services. Practising doctors and veterinarians are considered to be market-based for the purposes of the national accounts.

851209 Doctors, dentists, veterinarians

- The production value in 2007 was approx. DKK 33 billion measured at current prices
- 20 per cent of production is non-market
- Doctors produce only market-based services
- Dentists produce primarily market-based services
- Only public dental services are defined as non-market

Care home places, day centres and home help Sector 853209 Social institutions etc. for adults, shows data for care and social services for the elderly. This sector consists of two parts: the part that is considered as health care and the part that is considered as social services for adults and the elderly. The total production value in 2007 was approx. DKK 70 billion. Over 90 per cent of this total production is non-market and over half of the production is made up of health services for the elderly. Therefore the part that is considered as health care should be included in the calculations of volume indicators for health care.

853209 Social institutions etc. for adults

- The production value in 2007 was approx. DKK 70 billion measured at current prices
- Over 90 per cent of production is non-market
- Production consists of health and social services for the elderly

4.2 Output-based price index for health

This section describes the sources used to calculate the output-based price index for the health care services, and determines output-based price indices for the health care services in Denmark. The price index for the quantity of health care services, which is determined by equation 3.8:

$$P_{t,t+1}^B = \frac{\sum_i P_{t+1,i} * M_{t+1,i}}{\sum_i P_{t,i} * M_{t+1,i}}$$

As described above, health services in the national accounts are placed in three sectors covering widely differing aspects of health services. However, it is not just between sectors that services vary. Although the national accounting, SUT, contains about 2,350 product numbers, this level of detail is not always comprehensive enough to set up a price index.

Deflation of hospitals

Sector 85110 Hospitals contains only one product number for the production value of non-market hospital services. The new constant price regulation involves requirements for special deflation of somatic hospitals. Therefore, it is necessary to draw on more detailed information in order to perform a constant price calculation, which takes into account the price growth for hospital services.

The internal database for public accounts provides the source data for calculating the non-market production value in the national accounts. However, this data is aggregated in the national accounts and needs to be distributed in more detail. Table 4.1 shows an extract from the internal database regarding the services classified as health-related spending according to COFOG, the international classifications registry (Classification of the Functions of Government).

The following three COFOG groups are included in the non-market product number for hospitals:

- 0731 General hospital services
- 0732 Specialised hospital services
- 0734 Nursing and convalescent home services

The entire production of general and specialised hospitals is included, only a very small proportion of the total production value of 0734 Nursing and convalescent home services is included.

Table 4.1 Non-market production of health services 2007

COFOG		DKK mill.	per cent share
0713	Therapeutic appliances and equipment	978	1
0721	General medical services	5	0
0723	Dental services	2 094	2
0724	Paramedical services	3 738	4
0731	General hospital services	69 215	67
0732	Specialised hospital services	6	0
0734	Nursing and convalescent home services	21 570	21
0740	Public health services	1 343	1
0750	R& D health	20	0
0760	Health n.e.c.	4 058	4
070	Total health	103 026	100

This information provides grounds for deflating the product number for hospitals via two indices: one for general hospitals, and one for specialised ones. These two indices are weighted with their respective production values from the COFOG classifications.

Public dental services

Non-market production in sector 851209 Doctors, dentists, veterinarians is deflated via two indices: one measuring the price growth for public dental services, and one for general hospital services. The dental services index is used to deflate the product number for non-market dental treatment, which is largely identical to the production

value for COFOG classification 0723 Dental services. One other non-market product number is included in this sector. This contains general health services and is deflated using the price index for general hospitals.

*Health care for
elderly and
handicapped adults*

853209 Social institutions for adults include two non-market product numbers: one for nursing homes, day centres and so on, and one for social institutions for adults. Among other things, the former consists of the entirety of 0734 Nursing and convalescent home services, and other services not classified as health services. Hence a weighted price index for nursing homes, etc. is used to deflate this product. A product number for residential institutions for handicapped adults is also deflated using the index for nursing homes, etc.

The following section describes the price index used to deflate the individual health services. These sections provide a detailed description of how the price indices are calculated. The price indices are as follows:

- Price index for somatic hospitals
- Price index for public dental services
- Price index for residential and day care places for the elderly

4.2.1 Price index for somatic hospitals

The price index for general hospitals is the individual index used to deflate the largest value among health services. In 2008, it was used to convert the production values for over DKK 70 billion. The price index thus has a decisive influence on the price and volume growth for the non-market economy. In fact, this index is given so much weight that a major change in the deflator is directly reflected in economic growth.

The price index for general hospitals is calculated on the basis of the Danish National Board of Health's Diagnosis Related Group database (DRG). In Denmark, this system is used as a tool for calculating fees to settle the accounts of patients treated in a different municipal area from the one in which they reside. The central health authorities and hospital owners also use the system to assess the correlation between activity and costs in hospital services. Finally, it is increasingly used for budgeting and, particularly, as a tool for developing new methods of premises planning and management in administration and hospitals.

The fact box provides a brief outline of the DRG system and what it involves. For a detailed description, please see the Danish National Board of Health's website, www.SST.dk, which contains a vast amount of information about the DRG system.

The DRG system contains information about the number of treatments and the associated fees for about 800 different types of treatment. Table 4.2 shows an excerpt from the existing data. In this case, the data is distributed according to a range of established main categories, known as MDC classification. Data is displayed at this level solely for presentation purposes. All underlying data contains information about prices (the fee) and volumes (the number of treatments) for each individual type of treatment.

Starting with this material, which provides information about prices and volumes, it is possible to calculate a price index for general hospitals. As mentioned above there are some inconsistencies in data between 2006 and 2007, where the Danish National Board reorganised the DRG groups, because of this the two years are not fully comparable.

*Calculating price
indices based
on DRG data*

Based on this data, price indices are calculated according to the method outlined in chapter 3. Since all treatments, j , cannot be compared between periods, partly as a consequence of new treatments, only those prices and volumes, i , that are comparable are used. When equation 3.8 is applied to DRG data, a price index for the period 2005 to 2006 can be calculated as:

$$P_{2005,2006}^B = \frac{42,067,878}{42,994,101} = 0.978$$

The price for general hospital treatments between 2005 and 2006 decreased 2.2 per cent.

Table 4.2 shows the price development for the periods 2001 to 2008 calculated according to the above method, using the DRG data, which is comparable between two consecutive periods. The table shows that in four out of six years, it was on average less expensive to perform an equivalent treatment in the following year.

Table 4.2 Price change for general hospitals

	2001	2002	2003	2004	2005	2006	2007	2008
	per cent annual growth							
Price change for general hospitals	-0.2	-0.4	1.9	-1.6	1.7	-2.2	2.2	1.3

*Manual changes
to DRG data
and data set percentage*

The data set percentage is a measurement of the proportion of the data that is comparable between two consecutive years. Data can be either directly comparable or made comparable due to manual changes. In 2001 the data set percentage is thus the value that is included in the calculation for 2001 compared with the total value in 2000. In order to be included in the 2001 calculation, the treatment must exist in both 2000 and 2001. 99.8 per cent means that treatments representing 0.2 per cent of the value in 2001 cannot be retrieved for 2000. Table 4.3 shows an overview of the number of series that are comparable between two consecutive years, and the size of the data set percentage.

Table 4.3 Comparable DRG data

	2001	2002	2003	2004	2005	2006	2007	2008
Data set percentage	99.8	97.1	93.1	89.4	96.7	92.5	71.0	97.5
No. of series	603	627	595	530	660	660	416	583

2001 and 2002 have high data set percentages, because the DRG data for 2000, 2001 and 2002 contains the same DRG codes. This implies that it was not necessary to perform manual corrections in calculations between these years. As pointed out above, there were large inconsistencies between 2006 and 2007 and we needed to make many manual corrections, to achieve a more comparable data set over time and thus more series were included in the calculations of the indices. But there was no big difference in DRG's between 2007 and 2008, which means that many manual corrections were not necessary in that case. However, the number of series that are comparable between 2006 and 2007 is only 71 per cent, but by the manual corrections we reached a comparability share about 90 percent. Comparability share has consequences for the calculation of volume indices and price indices below.

During 2003 and 2004, the DRG system was subject to an increasingly detailed division of treatments. This improvement to the system, however, has the short-term disadvantage that the number of matching groups between two years is reduced. As described later, comprehensive chaining work was performed between these years, which reduced transitional problems. However, both the data set percentage and the number of indices are still lower during these years.

Deleted series A range of data was deleted in the individual calculation years as a consequence of highly contradictory price indices. Data is omitted during specific years based on the following criteria:

- Major price changes – typically doubling from one year to the next
- Substantial price fluctuations along with substantial variations in volume

In this way, series with substantial price fluctuations (typically up to +/-50 per cent) can still exist if the volume growth is stable. Similarly, series with ongoing major price fluctuations, but for which the volume changes only moderately, may occur.

Sensitivity study A sensitivity study – in which all remaining indices over 1.5 and below 0.66 are deleted – disclosed the fact that the overall index did not change to the fourth decimal point. Consequently, the remaining extreme index has a very minimal effect on the overall index.

4.2.2 Price index for public dental services

Public dental services are the least valuable sector for which a direct price index is calculated. In 2008, non-market production from dental services totalled DKK 2.2 billion.

A special extract from the Social Resource Statistics⁵ (Den Sociale Ressourcestatistik) provides details concerning the number of people receiving treatment. The number of people receiving treatment is distributed across dental services and orthodontic treatment. The data also indicates whether the treatment was provided as a public dental service or by a practising dentist. Table 4.5 provides an overview of the number of people receiving dental treatment.

Table 4.5 **Number of treatments**

	2000	2001	2002	2003	2004	2005	2006	2007	2008
	quantity								
Public dental clinics	1 017 108	1 029 793	1 047 736	1 056 242	1 064 980	1 069 276	1 076 184	1 068 531	1 107 196
Dental services:									
practising dentists	160 838	163 238	165 518	169 253	168 258	171 524	171 902	151 252	141 120
Orthodontic treatment:									
public clinics	13 579	14 474	14 785	14 974	15 448	15 911	16 389	16 880	17 834
Orthodontic treatment:									
practising dentists	2 270	2 506	2 375	2 511	2 721	2 830	2 943	3 061	3 183
Total	1 193 795	1 210 011	1 230 414	1 242 980	1 251 407	1 259 541	1 267 418	1 239 724	1 269 333

The costs for these treatments are from internal databases. The detailed COFOG code 0723 Dental services include costs for non-market dental treatments.

The internal data does not specify whether the costs are associated with dental treatment or orthodontic treatment. This is problematic as orthodontic treatment requires more resources than dental care. The amount of resources devoted to the two types of treatment has been estimated, using accounts from the municipalities of Helsingør and Stevn. The studies show that two thirds of the costs are associated with dental care, while the rest goes to orthodontic treatment. Using this information, the total costs were distributed across dental care and orthodontic treatment respectively.

⁵ Published by Statistics Denmark

Table 4.6 Costs associated with dental treatments

	2000	2001	2002	2003	2004	2005	2006	2007	2008
	DKK 1000								
0723 Total dental services	1 632 846	16 680 753	1 799 522	1 830 640	1 864 825	1 945 548	1 943 264	2 012 542	2 107 958
Dental care	1 088 564	1 120 502	1 199 681	1 220 427	1 243 217	1 297 032	1 295 509	1 341 695	1 405 305
Orthodontic treatment	544 282	560 251	599 841	610 213	621 608	648 516	647 755	670 847	702 653

With information about costs at the detailed level, it is possible to calculate a fee for dental care and orthodontic treatment. The detailed costs divided by the number of treatments produce the fee for the year, cf. table 4.7.

Table 4.7 Calculated fee for dental treatments

	2000	2001	2002	2003	2004	2005	2006	2007	2008
	DKK per treatment								
Dental care	924	939	989	996	1 008	1 045	1 038	1 100	1 126
Orthodontic treatment	34 342	32 995	34 956	34 899	34 213	34 604	33 507	33 641	33 432

By means of the prices in table 4.7 and the volumes in table 4.5, it is possible to calculate a price index for non-market production of dental services. This method is again the same as that outlined in chapter 3. Table 4.8 shows the calculated price index. Between 2000 and 2001, the implicit prices of dental treatment fell slightly, while there were subsequent price increases of between 0.4 per cent and 5.5 per cent annually. The price index fell again in 2006.

Table 4.8 Price increase for dental treatment

	2001	2002	2003	2004	2005	2006	2007	2008
	per cent annual change							
Price increase for dental treatment	-0.3	5.5	0.4	0.9	2.5	-1.5	4.0	1.3

4.2.3 Price index for residential and day care places for the elderly

Sector 853209 Social institutions for adults, consists of both non-market care for the elderly and other non-market services for the elderly, e.g. non-nursing residences and so on. The part considered as “care” is classified as a health service in COFOG, and therefore should be included in the calculations of volume indicators for health and education. The price index for nursing and day care places for the elderly is very important, since the production value for nursing and convalescent homes in 2007 was approx. DKK 22 billion.

Calculation of price index

The Social Resource Statistics provide details concerning the number of elderly people, who have a place in a nursing home, and the type of care involved. During this period, there was a steady drop in the number of nursing home places. This is due to reprioritising, which means that nursing home places have been converted or discontinued in favour of homes for the elderly. According to the Danish industry codes⁶, homes for the elderly belong to a sector for adult social care. Thus they are included in the following chapter and not in these calculations.

⁶ Dansk Branchekode 2003 (Danish Industry Codes 2003). Statistics Denmark 2002.

Social centres	4 322	4 330	4 472	4 406	3 722	3 766	-	-

Data from Copenhagen City's accounts was used to source the prices for individual residences. These accounts show the realised unit costs for each type of residence. Because it is currently not possible to retrieve unit costs from other counties, the price growth in Copenhagen City has been assumed to be representative of the entire country. Table 4.10 shows the unit prices distributed according to the type of care place between 2000 and 2008. Copenhagen City first began to present its actual realised unit costs in the 2001 accounting year. For this reason, the unit costs for this year are based on retrospective calculations based on the overall growth. In 2006 Copenhagen City began to make up the unit costs for individual residence in a new way, which implies that it is not possible to compare unit prices before 2006 and after. For this reason, the unit costs from 2006 to 2008 are based on retrospective calculations based on the overall growth.

Table 4.10 Unit prices for residential and day care places for the elderly

	2000	2001	2002	2003	2004	2005	2006	2007	2008
unit prices									
Nursing homes/residences	321 714	329 000	338 000	340 000	346 820	361 549	386 315	379 612	398 273
Sheltered housing . .	126 143	129 000	132 000	132 000	134 215	139 375	141 466	144 295	147 181
Elderly homes	80 429	82 250	84 500	85 000	86 705	90 387	96 579	94 903	99 568
Social centres	157 435	161 000	165 000	165 000	167 768	174 218	176 831	179 484	182 176
Day centres	39 114	40 000	41 000	41 000	41 942	43 555	44 208	44 871	45 545

Starting with the prices and volumes, it is now possible to perform a price index calculation analogous to the one in chapter 3. The price growth for residential and day care places for the elderly varies between -1.6 per cent and 6.3 per cent in the period, cf. table 4.11.

Table 4.11 Price increases for residential and day care places for the elderly

per cent annual growth								
Price increase for residential and day care places for the elderly.	2.3	2.7	0.5	2.0	4.2	6.3	-1.6	4.8

4.3 Quality of health care

This section will consider some important aspects of health care output and propose some indicators and methods to calculate the non-market health care output at constant prices using the output method with quality adjustment. According to Eurostat's present guidelines, this is an A method and, therefore, the most appropriate method. The focus here will be on determining quality indices for health care and then equation 3.12 will be used to calculate a quality adjusted output-based price index.

One of the major difficulties in calculating volume indices is the quality change of the products. In health care services, new treatments and new drugs are constantly introduced whereby the outcome and quality of treatments change. An important question arises; how can we compare the quantity of health services produced in a given year with those produced in the preceding year, if some services did not exist in the previous year or have changed?

As pointed out in chapter 2, measuring quality is very complex and depends on many subjective assessments and decisions. In this publication, we will discuss and describe the potential Danish indicators and illustrative quality adjustment figures will be presented.

4.3.1 Measuring the change in quality of health care

Quality indicators

There are a number of desirable characteristics of indicators that could be used for quality adjustment for volume output with the aim to determine the marginal contribution of the health care service to the outcome. Since we are interested in health outcome improvements over time, the outcome indicators used for quality adjustment should be consistent over time and, if possible, updated annually. Quality indicators should reflect all changes in the health service as a whole, i.e. they should reflect areas where the marginal contribution of the health care service is either positive or negative. It is generally suggested that the optimal indicator set should contain both process and outcome measures. Moreover, the indicator set should be based on three main criteria; the importance, the scientific soundness of the measure and, the availability of sufficient data.

This section discusses aspects of quality in health care services and proposes a conceptual model to be used in this theme publication. The focus will be on the following two central quality aspects, i.e.;

1. The extent to which the public services succeed in delivering the intended outcome
2. The extent to which the service corresponds to users' requests.

The following indicators will be considered when looking at the extent to which the public services succeed in delivering the intended outcome:

- Health gain as consequence of hospital treatment
- Reduced mortality rates/ increased survival rate
- Health gain as a result of reduced waiting times
- Preventive arrangements
- Centralization/specializing the hospitals

Health gain

Health gain is the pattern of health status over the rest of the patient's life, compared with health status if the treatment had not been given. Health gain can be achieved even if patients do not get better, since for some conditions the best that can be expected, even with good treatment, is a less rapid decline in health status towards unavoidable death. Furthermore, health care can relieve pain and other symptoms and extend life.

<i>Reduced mortality rates/survival adjustment</i>	Data on deaths within 30 days of admission, by hospital procedure is generally accepted as a quality measure. Death from a condition from which a patient should recover is an important indicator of quality (or failure). For instance, the death rate of patients admitted with acute disease, such as appendicitis, is considered to be a good quality indicator. Comparisons of death rates have to be adjusted for case mix – age of patient, severity of diagnosis, morbidity and other risk factors.
<i>Waiting times</i>	The experience of waiting for treatment plays a part in both the health gains and patient experience aspects of quality of health care. Longer waiting time for treatment may reduce health gains; patients defer the benefits of treatment, and may have pain, reduced mobility, concern and other damage to their health status while waiting, and in that way their health gain from treatment will be reduced. Hence, a reduced waiting time is considered a health gain.
<i>Preventive arrangements</i>	Health gain from primary medical care is regarded as one of the most important preventive arrangements. The purpose of preventive health care services is to improve the overall health of the population, and it is considered a very important factor of the health care services. The medical/clinical outcome could be improved by controlling diseases as high blood pressure, hypertension, asthma, cholesterol, stroke and diabetes to avoid premature death. Most of these illnesses are chronic, i.e. long-term and many cannot be cured, but they can be controlled. At primary health care level, the service is primarily based on prevention by informing patients about the benefits of a healthy lifestyle and by drugs.
<i>Danish data on preventative arrangements</i>	Only little data is available for preventive arrangements. The National Board of Health has data about the asthma mortality rates covering the analysis period. Also, the National Board of Health has started to register the data about the primary care of diabetes, but since this data is new, it does not cover the analysis period of this publication, but may be applied in later publications. The asthma mortality rate is the only quality indicator for preventive treatments that will be applied in this research.
<i>Centralization</i>	Denmark has experienced a centralization of hospitals. One of the main goals was to concentrate the expertise in a few, central hospitals. For instance, the small, provincial hospitals no longer were allowed to perform complicated surgeries. At the moment, there is no scientific measurement of the effects of the centralization, but the general experience among experts is that it saves lives and results in more health-gain. A disadvantage of this policy is that some patients have a longer distance to the hospital. However, in Denmark we do not have any data for centralization degree yet.
<i>Consumer needs</i>	<p>The other aspect of quality is related to the use of health care services; does the service respond to users needs? The following quality indicators will be included in this theme publication,</p> <ul style="list-style-type: none"> • Patient experience • Waiting time
<i>Patient experience</i>	Patient experience is usually measured through surveys. Survey questions are often grouped into different domains, including better information to the patients and their relatives, more choice, possibilities and safe, coordinated, high quality care. The collaboration between health care system and patients is also considered as an important quality factor. Surveys measure different areas of the health care service, for example; hospital inpatients, mental health, and primary care. The weight given to patient experience is assumed to vary across areas. Patient experience is assumed to be relatively more important for primary care and for mental health services than for hospital inpatient, outpatient and accident and emergency services.

Waiting times The knowledge of waiting for treatment plays a part in both the health gains and patient experience aspects of quality of health care. Firstly, they may dislike waiting; waiting may be a bad experience for patients even when they are not in pain. Secondly, longer waiting time for treatment may reduce health gains; patients defer the benefits of treatment, and may have pain, reduced mobility, concern and other damage to their health status while waiting, and in that way their health gain from treatment will be reduced.

4.3.2 Quality indicators for Danish health care services

The quality indicators used to quality adjust the health care volume in this publication are given below

- AMI 30-day mortality rate
- Hemorrhagic stroke 30-day mortality rate
- Ischemic stroke 30-day mortality rate
- Cervical cancer five-year relative survival rate
- Breast cancer five-year relative survival rate
- Colorectal cancer five-year relative rate
- Asthma mortality rate
- In-hospital waiting time for hip fracture surgery
- Surveys of patient experience
- Waiting time

The first seven indicators relate to the in-hospital health gain, i.e. the information on success in delivering health gain. Since we only have quality indicators for a very small part of the DRG groups, only the DRG's that have these quality indicators will be quality adjusted, i.e. the effects of quality will not be fully reflected in the health care volume output.

An alternative option is to apply the above indicators as measure for quality in all DRG groups, but in this publication we have applied partial quality adjustment, i.e. only DRG groups with relevant quality indicators are quality adjusted.

Survival rates The above survival rates are used to quality adjust the related DRG's. The weight 0.6 is given to these indicators, since surviving such diseases are regarded as more important than patient experience and waiting time. There was no available information about waiting time for these DRG's, and we have chosen to give the survival rates the weight 0.6 and patient experience the weight 0.1. However, this is an assumption and it may vary with enhanced arguments. We believe that it would not be possible to measure the quality perfectly, i.e. a hundred per cent and there will always be some unmeasured factors left, either because they cannot be measured or because they cannot be observed.

Decrease in heart attack mortality rate Figure 4.1 shows the patient-based AMI (heart attack) 30 mortality rate for the period between 2001 and 2006. The mortality rates are decreasing over the period, meaning that the quality of the treatment is increasing.

Figure 4.1 Patient-based AMI 30-day mortality rate

*Waiting time
as an indicator*

The National Board of Health has waiting time data for some diseases and the Board is used to quality adjust the health care services. The waiting time for, e.g. cataracts operations, is regarded as average waiting time for the MDC group 2, Eye and waiting time for kidney diseases is regarded as an indicator for waiting time for the MDC group 4, Respiratory System. The weight 0.4 is given for these diseases since the dead frequency is very low for this MDC group, waiting time may then weight more than in diseases with higher dead frequency. For diseases with high frequency the waiting time may weight less. In-hospital waiting time for hip fracture surgery is also used as a quality indicator for all DRG's related to these diseases.

*Patient experiences
in this publication*

In this publication patient experiences are also regarded as a central quality element of health care output. Patient experience is measured through surveys commissioned by the Unit of Patient-Perceived Quality, The Capital Region of Denmark. The objective of the surveys is to compare patient experiences over time, and the survey includes questions about clinical services, patient safety, communication, information, progress of treatment, cooperation, physical surroundings, waiting time and free hospital choice. In this publication, the questions are divided into four main areas, information, cooperation, waiting time and quality. The surveys were conducted at two-year intervals in the period between 2000 and 2006.

The relative importance of patient experience to health gain may vary by diseases or situation. Here, patient experience is assumed to be less important for diseases where the frequency of dead is higher and for emergency cases, but more important in situations where treatment is part of a regular relationship. In this publication, the patient experience is given weights 0.1 for diseases with high dead frequency and 0.4 for disease with low dead frequency and regular relationship.

An essential question about quality adjustment is; how do we quality adjust in practise? The example below demonstrates how we calculate quality adjusted output-based price indices all DRGs concerning heart attack.

Example

Decrease in heart attack mortality rate

The figure above shows the patient-based AMI (heart attack) 30-day mortality rate for the period between 2001 and 2006. The mortality rates are decreasing over the period, meaning that the quality of the treatment is increasing.

Patient-based AMI 30-day mortality-rate

The quality index for heart attack is calculated in the following way; the changes in Patient-based AMI 30-day mortality rates illustrated in the figure and patient experience are used as quality indicators for the period 2001 to 2006. The data shows a fall in mortality rate and improvements in patient experience, implying that both indicators contribute positively to the quality.

A drop in mortality rate, i.e. an increase in quality contributes negatively to the price index, since a drop in the price index contributes to an increase in the volume of output, i.e. improvements in quality implies lower price index and higher volume of output. The same is suitable for increases in patient experience and thus an increase in quality contributes negatively to the price index and accordingly contributes positively to the volume growth. For that reason the changes in patient experience enter negatively to the quality index.

The table below shows calculations for the quality index for heart attacks in detailed level; the first two rows show the changes in mortality rate and patient experience, respectively. As described, since both factors contribute positively to the quality, they thus contribute negatively to the price index. Rows three and four show the weight given to the two factors, respectively, where row five gives the joint contribution for this to factors to the quality index. Row six shows the quality index for heart attacks, calculated by adding 1 to the contribution factor in row five. Row six reports price changes from quantity effect, while row seven shows the quality-adjusted price growth in per cent.

As stated before, the weight given to the quality indicators is based on subjective assessments, and the idea behind this assessment is that it is not and will not be possible to cover the quality hundred per cent, and indicators that we have are important and therefore they may cover about 70 per cent of the full quality.

Quality index for heart attacks

	2001	2002	2003	2004	2005	2006
Changes in for patient-based AMI 30- day mortality rate	-9.0	-7.1	-3.3	-8.4	3.4	-0.5
Change in patient experience	1.0	1.0	-1.9	-1.9	-0.3	-0.3
Weighting factor for mortality rate	0.60	0.60	0.60	0.60	0.60	0.60
Weighting factor for patient experience	0.10	0.10	0.10	0.10	0.10	0.10
Contributing factor	-5.3	-4.1	-2.2	-5.2	2.0	-0.3
Price change from quality effect	-5,3	-4,1	-2,2	-5,2	2,0	-0,3
Price change from quantity effect	0,4	-0,4	1,1	-8,6	13,3	-3,9
Quality-adjusted price increase	- 4.9	-4.4	-1.1	-13.4	15.6	-4.2

Quality index for general hospitals

The quality adjusted output-based price indices for general care are calculated from equation 3.12

$$P_{t,t+1}^B = \frac{\sum_i P_{t+1} * M_{t+1} * F(q_{t+1})}{\sum_i P_t * M_{t+1} * F(q_t)}$$

F is of function of quality, and quality is composed of different indicators, which are selected and weighted according to their importance (subjective assessment). The quality adjusted output-based price index for the period 2005 to 2006 can be calculated as:

$$P_{2005,2006}^q = 0.978 * 0.998 = 0.976$$

The first part of this equation is the cost index calculated in section 4.2 (quantity) and the second part is a quality index for general hospitals calculated by the same method as the quality index for, e.g. heart attacks, but this one covers all the DRG-groups. The quality index for general hospitals is calculated by weighting different quality indicators in the following way; the DRG's are partially quality adjusted with survival rates, i.e. only DRG's with a corresponding survival rate are quality adjusted with this indicator, and it is given the weight 0.6. The DRG's are also partially quality adjusted with respect to waiting time, since only few MDC groups had an indicator for waiting time and the weight 0.1 is given to this indicator. On the other hand, all DRG's are quality adjusted with respect to patient experience and the given weight is 0.1. The quality indices are calculated by the same method as the quality indices for heart attacks shown above.

The indices based on the output method with and without quality adjustment for the hospital services are given below (table 4.13). The quality adjusted indices grow at a lower rate in four out of six periods, while it grows faster in the two first periods, indicating that the quality adjustment contributes positively to the output volume in four periods with lower price indices. But this result should be regarded with caution, since the indicators are only partially quality adjusted, and the choice of weight given to the indicators is both subjective and can result in other indices if the criteria change.

Table 4.13 Comparison of price indices *with* and *without* quality adjustment

Price changes for:	2001	2002	2003	2004	2005	2006
	per cent annual growth					
General hospitals						
Output-based	0.2	-0.4	1.9	-1.6	1.7	-2.2
Output-based with quality adjustment.....	1.0	-0.2	1.2	-2.3	1.6	-2.4

5. Social protection services

This chapter describes the sources used to calculate the output-based price index for the social protection services.

The Danish social protection services are also very extensive and divided into several areas. The areas that will be treated here are:

- Sickness and disability
- Old age
- Family and children.

<i>Sickness and disability</i>	In the case of sickness and disability, when the number of people receiving services and care is distributed according to the level of care and services, this is classified as an A method. If the total number of people receiving care is used but not distributed according to level of care, this is classified as a B method. Where there is no quality adjustment, this is also classified as a B method.
<i>Old age</i>	The same is valid for old age. When the number of people receiving services and care is distributed according to the level of care and services, this is classified as an A method. If the total number of people receiving care is used but not distributed according to level of care, this is classified as a B method.
<i>Family and children</i>	In the case of family and children, when the data is quality adjusted, it is classified as an A method. If no quality adjustment is made, this too is classified as a B method.
<i>Quality of the social protection services</i>	This chapter will try to outline some of the key quality issues of the public social services, i.e. we will briefly discuss the possible quality aspects of those services and suggest some indicators to measure quality over time.

5.1 Non-market production of social protection in the National Accounts

Non-market production of social protection is produced in two main sectors, namely:

- 853109 Social institutions children and young persons
- 853209 Social institutions for adults

Sector 853109 Social institutions children and young persons includes crèches, kindergartens, after-school centres, special educational assistance, foster families, residential homes for children or young persons, preventive arrangements and so on. Approx. 80 per cent of the total production is non-market and is made up mainly of social services to children and young persons and consists of pre- and after-school activities as kindergartens and after-school centres, and preventive and residential offers for children and young persons with any kind of social problems and disabilities.

853109 Social institutions children and young persons

- The production value in 2006 was almost DKK 50 billion measured in terms of the prices for the year
- The entire production value is non-market
- Social institutions children and young persons include figures for crèches, kindergartens, after-school centres, and foster families, residential homes for children or young persons and so on.

Sector 853209 Social institutions etc. for adults, includes data for care of the elderly, which is classified as a health service and social service. Over 90 per cent of this total production is non-market and is made up primarily of health services and cost of rest homes for the elderly. The part of this sector that is related to health care for the elderly is treated above in chapter four (approx. 35 percent of the total prod.), and this chapter calculates volume indicators for the other part of this sector considering social services, which includes rehabilitation, special educational assistance, and help for practical purposes.

853209 Social institutions etc. for adults

- The production value in 2006 approximately DKK 60 billion measured in terms of the prices for the year
- Over 90 per cent of production is non-market
- Production consists almost exclusively of health services for the elderly and disabled adults

5.2 Output-based price index for social protection

This section describes the sources used to calculate the output-based price index for social protection services and determines output-based price indices for the social protection care services in Denmark, i.e. the quantity part of the output will be calculated according to 3.8.

As illustrated above, the social services in national accounts are placed in two sectors. The accounts database for public accounts provides the source data for calculating the non-market production value in the national accounts. Since this data is aggregated and needs to be distributed in more detail, Table 5.1 shows an extract from DIOR regarding the services classified as social protection-related according to COFOG.

Three COFOG groups are included in the non-market product number for social protection, i.e. in practice, this division means that individual indices are calculated for. The COFOG groups are:

- 1012 Sickness and disability
- 1020 Old age
- 1040 Family and children.

Table 5.1 Non-market production of social protection 2006

COFOG		DKK mill.	per cent share
1012	Sickness and disability	26 025	24
1020	Old age	12 682	11
1040	Family and children	48 789	44
1050	Unemployment	9 238	8
1060	Housing	85	0
1070	Social exclusion n.e.c.	4 046	4
1090	R&D Social protection	9 538	9
1000	Total social protection	110 450	100

5.2.1 Price index for Social institutions for children and young persons

Due to the reform in the local governments we are yet not able to obtain data that is consistent from 2006 to 2007. It is primarily the number of activities, where the data break is highest i.e. data cannot be compared between the two periods. Therefore this publication will not publish any social protection data for 2007 and 2008. But we will aim at presenting a time-consistent data series in the next publication.

Sector 853109 Social institutions for children and young persons, consists primarily of non-market services for families and children and of institutions such as kindergartens and after-school activities for children and young persons. This sector also includes offers for children and young people with special needs, for instance foster families and residential homes as well as preventive arrangements. Table 5.2 shows the number of places in different kinds of institutions. The price index for social institutions for children and young persons is very important, since the production value in 2006 was approx. DKK 50 billion.

The Social Resource Statistics provide details concerning the number of children and young people in the different institutions.

Currently, it is not possible to find any representative key fees for different types of institutions; therefore the costs for these services are given in the internal database. The detailed COFOG code 1040 Family and children includes costs for non-market social services for children and young persons. The internal data specifies the costs at the detailed level, so it is possible to calculate a fee for different types of services. The detailed costs divided by number of places at different institutions produce the fee for the year.

5.2.2 Social institutions for adults

Sector 853209 Social institutions for adults, consists of both non-market services for the elderly and different types of social services for disabled people with various needs. The part of Sector 853209 considered as “care” is classified as a health service in COFOG, and, therefore, is included in the calculations of volume indicators for health care in chapter 4. The part that is not considered “care” is classified as social protection services and treated in this chapter.

The Social Resource Statistics provides details concerning the number of people at different institutions and number of individual assistance hours, care and help for practical purposes given to the elderly and disabled people in their homes respectively.

Currently, it is not possible to find any representative key fees for different types of institutions, therefore the costs for these services are given in the internal database. The detailed COFOG code 1012 Disabled and 1020 Old Age includes costs for non-market social services adult. The internal data specifies the cost at the detailed level, so it is possible to calculate a fee for different types of services. The detailed costs divided by number of places at different institutions produce the fee for the year. Salary per hour for public employees for different service levels are multiplied by the number of hours worked to get a weighted price index for the part of service concerning service for elderly people. These two indices and the two COFOG codes are weighted with their respective production values from the COFOG classifications and the price index for social service for the adult is given in table 5.8.

5.3 Quality of social protection services provided by the government

The output-based measures can be improved by adjusting output in a way that takes into account the quality changes of the service provided over time. Principle B of the Atkinson Review stated that ‘the output of the government sector should be measured in a way that is adjusted for quality changes over time.

Social care is currently measured in the National Accounts equating input used to provide the services with output. This publication uses a cost-weighted activity index, which weights together growth in prices. The limitations of this approach is that:

- A measure based on activity fails to take into consideration changes of quality in the service provided over time.

The social protection expenses constitute a significant part of the government spending in Denmark, hence it is important to be able to measure the value of the services correctly, i.e. the output of the public services.

Adult social care The purpose of the adult social care is to meet the needs caused by old age and weakness by helping people with personal care and, to a certain extent, provide friendship for those who might be isolated, i.e. the main goal of social care is improvement of quality of life that people feel as a result of using the service. In Denmark, care for the elderly is primarily provided as home care and at nursing homes.

To measure the value of social care services correctly it is essential also to measure the changes over time, and measuring quality is not that simple; firstly, it is essential to define the quality aspects for the diverse services and, secondly, to identify the crucial indicators for those services. The quality of services in the case of social care for adults can be divided in two areas, namely the basic needs and the needs at higher domains.

Basic needs as:

- Accommodation
- Cleanliness and comfort
- Food
- Safety
- Personal cleanliness.

Needs at higher domains:

- Better quality of life, which includes involvement and control over daily life, dignity, activity and social participation.
- Involvement of the home residents in decision making.

Quality adjustment requires a system of weighting all quality aspects together in order to combine the different components to form a single quality indicator. But weighting of quality aspects together according to their relative importance is not that easy and another difficult and important issue is weighting of quality and quantity components together. For instance, should one percent change in quality imply one percent change in quantity? And who is best to make a judgement? (providers, users, experts or general public and preference studies etc.) It is also vital that the weight given to the different indicators can change over time, the importance of a given service may not be constant over time, it may change with the structure of the society and technically development etc.

Children's social care

Nursery houses, kindergartens and after school centres are the most common institutions, where children's social care services in Denmark are provided. This is related to the Danish labour market structure. Although it also includes plenty of special institutions for children and young people with special needs, for instance foster families and care homes.

One of the main goals for the high number of children's institution is to provide child care for children whose parents both work outside the home. At the same time, it is expected that children and young people join in a wide variety of high quality, positive activities developing their personal and social skills, i.e. by engaging children and young people in structured, positive activities and help them develop good personal and social skills, as well as giving them a better sense of well-being; thereby reducing risky behaviours. Most importantly; children should be ready to start school with appropriate skills and confidence.

Since the unit cost we have for these activities does not reflect the quality of those services given, that unit cost is based on producer valuation and not consumer valuation and the fact that quality of services changes over time. One of the most important quality aspects in the case of child care is the number of children per present adult, i.e. adjusted for absenteeism, etc. The more time spent on one child, i.e. fewer children per adult, the higher the quality is considered to be. But at the moment we do not have any empirical research that shows the optimal number of children per adult. Therefore, quality adjustment is necessary to reflect the 'true' value of the service. Below is a list of quality indicators that could be used to adjust social institution (for primary cares as nursery houses, kindergartens and after school centres) for quality over time:

- Child/educator (adult) ratio
- Staying safe
- Personal, social, physical and emotional and behavioural development
- Creative development
- Personal care routines
- Language, communication and reasoning
- Knowledge and understanding the world
- Family and social background

However, most of those indicators are difficult to measure in practice.

Another important part of child social care is fosters families, care homes and other special institutions for children with special needs, which are either related to their socioeconomic background or are congenital.

The quality changes for special institutions and homes could be measured by some of the indicator given below.

- Children per adult
- Children who are placed at foster families and children's homes and their obtained education level and exam results over time. For instance the share that has obtained a 9th grade exam, the share that finishes a high school and the share with and higher education.
- Personal, social, physical and emotional and behavioural development over time
- Labour market commitment, how well are they performing in the labour market over time
- Socioeconomic and demographic development

Measuring methods for social protection services

The mentioned quality indicators for social protection services are in general not easy to measure, it may require vast amounts of resources, but the most reasonable method may be observation by specialists and surveys.

6. Education

The approach of this chapter is, firstly, to define the direct outcome indicators of education, and, secondly, to look at the quality of education.

The education sector is extremely extensive in that it produces a long list of different types of education services. In order to measure the growth in prices and volumes accurately, data meeting the following criteria is required:

- Data must be completely or almost completely comprehensive
- Data should be stratified, so that it reflects both the level and focus of the education.

Therefore, A and B methods will cover entire or very large portions of the educational sector. Similarly, the data source will provide enough detail for the following categories to be covered:

- Pre-school education
- Schools for children and young people
- Education at post-secondary school level, both general and technical
- Education at institutes of higher education
 - University courses
 - Other higher education

In addition to being sufficiently stratified, data should also achieve a certain standard of quality. The pupil-hours, i.e. number of teaching hours, 1st best quantity index of the output according to Eurostat's handbook on volume and price. If data is quality-adjusted, the method is classified as an A method; if no quality adjustment is made, it is classified as a B method. In the case of further education, it is recommended that only the number of students/pupils is used to indicate volume growth.

All methods that are more closely linked to input rather than output are considered to be C methods. If the number of teaching hours is used to indicate the growth, this method is classified as a C method. Regardless of method, the same applies if data is not broken down to an appropriate level of detail.

6.1 Non-market production of education in the National Accounts

Public non-market education is produced in four sectors:

- 801000 Primary and lower secondary education
- 802000 Post-secondary and vocational education
- 803000 Institutes of higher education
- 804002 Adult education etc. (other non-market)

All areas producing educational services contain exclusively non-market services. Market-based educational services are placed in sector 804001 Adult education, etc. (market). This includes, e.g. driving and music schools.

801000 Primary and lower secondary schools

- The production value in 2007 was over DKK 52 billion measured in terms of the prices for the year
- The entire production value is non-market
- Private primary and independent schools are considered to be non-market for the purpose of the national accounts, since under half of their costs are covered by user payments
- The sector also includes figures for continuing education colleges and schools

Sector 801000 Primary and lower secondary education includes both general and private schools. Private primary and lower secondary schools are classified as non-market, since under half of their costs are covered by payments from the students themselves.

802000 Post- secondary and vocational schools

- The production value in 2007 was almost DKK 20 billion measured in terms of the prices for the year
- The entire production value is non-market
- The sector includes figures for post-secondary, higher preparatory exams, commercial colleges, trade schools, agricultural colleges, social and health education, and so on.

802000 Post-secondary and vocational schools includes both technical and general post-secondary schools by definition. The sector also includes a broad range of business schools along with social and health education. All education is classified as non-market.

803000 Institutes of further education

- The production value in 2007 was approximately DKK 22 billion measured in terms of the prices for the year
- The entire production value is non-market
- Institutes of further education include figures for universities, business schools, technical colleges, educational seminars, and police and defence schools and so on.

803000 Institutes of further education consists of both general and technical colleges and universities. Seminars, etc. are also placed here, as are training institutions linked to the police and Danish Defence.

804002 Adult educations etc. (other non-market)

- The production value in 2007 reached nearly DKK 8 billion measured in terms of the prices for the year
- The entire production value is non-market
- Institutes of further education include figures for folk high schools, workshop schools, labour market training and so on.

Sector 804002 Adult education etc. is the smallest of the non-market educational sectors. Institutions, such as folk high schools, workshop schools and various labour market training, including so-called AMU courses under the labour market training scheme, are placed in this category.

6.2 Output-based growth rate for education

The main objective of this section is to determine the output-based quantity index, which is calculated according to equation 3.8.

Educational services in the national accounts are, as previously stated, placed in four sectors covering the various educational levels available in the education system. All four sectors exclusively contain non-market activity. In contrast to health services, where it was necessary to draw upon data in the DIOR database to define the individual services, the product divisions in the national accounts contain sufficient information to identify the relevant products. For the sake of clarity, we have provided a table showing non-market production of educational services; see table 6.1 below.

Table 6.1 Non-market production of educational services. 2007

COFOG		DKK mill.	per cent share
0920	Primary and lower secondary education (0912 + 0921)	56 369	57
0932	Post-secondary and other mid-length education, and preparatory schools for tertiary education	19 691	20
0940	Tertiary education (0941 + 0942)	15 218	15
0950	Education not definable by level	4 444	5
0960	Subsidiary services to education	68	0
0970	R&D education	447	0
0980	Education n.e.c.	2 049	2
090	Total education	98 287	100

In the educational sector, non-market production is derived from five COFOG groups: 0920 Primary and lower secondary education, 0932 Post-secondary and other mid-length education, and preparatory schools for tertiary education, 0940 Tertiary education, 0950 Education not definable by level and 0980 Education n.e.c. There is a close correlation between the national accounts 130 industry classification and the COFOG classification of educational services. This is as follows:

- 0920 Primary and lower secondary education is placed in 801000 Primary and lower secondary education
- 0932 Post-secondary education etc. is placed to 802000 Post-secondary and vocational education
- 0940 Tertiary education is linked to 803000 Institutes of further education.
- 0950 Education not definable by level is linked to 804002 Adult education etc. (other non-market)

Information will be used to distribute the calculated index so its scope corresponds to the above. The various price indices calculated are as follows:

- Price index for primary and lower secondary education
- Price index for post-secondary education
- Price index for tertiary education
- Price index for adult education

In contrast to the health sector, in which a range of different sources were used to calculate the various price indices, the education sector is much more homogeneous. The volume data for the four price indices are all derived from one source. This source is Statistics Denmark's Education Register, which contains information about the number of students/pupils undertaking the various types of education.

<i>Sources for calculation of prices</i>	Market prices do not exist for educational services. However, the individual educational institutions are subsidised by the government according to the number of students passing the relevant course. This payment is made according to a detailed annual fee directory, which contains fees for many different courses. The fees are published each year in the annual Danish budget. These fees are the best indication of prices for educational services and will be used for all types of education, except for public primary and lower secondary education.
<i>Data on the number of students/pupils</i>	In Statistics Denmark's databases each student/pupil is given a code for according to type of education as well as a proprietary code, specifying whether the education is private or public and whether it is a course. In this context, "private" should be understood as private schools producing non-market services. As previously described, private schools represent non-market production, since the user payments cover less than half of the costs for the service. ⁷ This division is relevant, since the fee differs, depending on whether the school is private or public. In the case of part-time study, the quantity is made up of student years, i.e. data is compiled in terms of full-time study.
<i>Alternative data on the number of hours taught.</i>	In the case of primary, secondary and post-secondary students, a more accurate measurement of volume is the number of hours during which students were taught. This information is not available from Statistics Denmark's Education Register. UNI-C has started to register this information, but they do not cover the period of analysis treated in this theme publication. The calculations for primary and secondary education are thus based on a less accurate measurement of volume: the number of students. There are no educational codes in Statistics Denmark's Education Register or the annual Danish budget that enables these prices and volumes to be linked. Comprehensive manual intervention was required to produce a link between the two sources. One key connection between the two sources is produced from an objective code, CØSA, under budget code FSP1E. Based on this transition key, the annual Danish budget fees can be linked in the Education Register. This provides information about prices and volumes for all types of education calculated according to fees in the annual Danish budget.
<i>Special calculation for public primary and lower secondary education</i>	The annual Danish budget does not contain fees for public primary and lower secondary education; hence the fee for this has been calculated on the basis of the total costs for primary and lower secondary education. This is available from the published accounts under COFOG classification 0920; cf. table 6.1. This figure is divided by the total number of pupils in primary and lower secondary schools, producing a fee for public primary and lower secondary education.
<i>Calculation of growth rate</i>	The data set, in which prices and volumes are linked, is now used to calculate the price indices for the four different educational services. Based on the educational codes, it is possible to identify the indices in which individual observations should be included. The method outlined in chapter 3 is used to calculate the price index. To calculate a specific index, the types of education, i , which needed to be included in the calculation of the relevant index, were selected from all the observations, j , using equation 3.8 is used to calculate the growth rate for primary and lower secondary education the following result is produced:

$$P_{2005,2006}^B = \frac{36,802,396,504}{35,768,212,982} = 1,029$$

⁷ See chapter 3

The growth rate of prices for primary and lower secondary education between 2005 and 2006 was 2.9 per cent.

Table 6.2 Price change for education

	2001	2002	2003	2004	2005	2006	2007	2008
	per cent annual growth							
Price increase for prim./lower sec. ed.	4.4	3.7	3.2	2.7	3.3	2.9	0.9	3.8
Price increase for post-secondary education	4.0	2.4	5.1	-1.2	4.6	0.5	-0.4	1.5
Price increase for tertiary education	1.8	0.6	4.4	-0.5	0.8	-0.4	1.7	1.5
Price increase for adult education	2.9	1.8	6.5	-8.8	-0.7	-0.7	0.5	1.5

The other three price indices are similarly calculated. Table 6.2 shows a total overview of the price indices for educational services between 2000 and 2008. The change in the price index for primary and lower-secondary education varies between 4.4 in 2001 and 0.9 in 2007. The data for post-secondary education shows that the prices for this service varied between a price drop of 1.2 per cent and a price rise of 5.1 percentage point. For tertiary education, the growth rate of price was calculated at between 0.5 per cent and 4.4 per cent, while adult education varied between a price drop of 8.8 per cent and a price rise of 6.5 per cent. This is probably due to the fact that the composition of adult education is rather different when compared with other educational services.

6.3 Quality of education

In the previous section, the quantity/volume of education was calculated. In this section the quality aspect of education will be discussed and possible quality indicators will be introduced. Possible quality indices will be determined and then quality adjusted price indices will be calculated based equation 3.12.

The education output The main quality component of the output of an education system is the sum of the expected transfers of knowledge and skills towards all pupils, i.e. the total transfer of knowledge and skills performed by education.

The aim of education is to improve knowledge and skills, i.e. put the pupil's potentials to maximum use. Education has a positive effect on the economic well-being of individuals and society as a whole, since there is a strong causal relationship between education, earnings and productivity. Educated (highly educated) citizens generate higher tax incomes for the government, because highly educated people earn a higher wage than people with lower education, and thus pay higher taxes during their lifetime.

In general, education outcome is considered to depends on three components:

- Natural abilities, knowledge and skills attributable to the socio-economic background
- Motivation and work effort from the student
- Knowledge and skills transferred by the education institutions

Since the purpose of this publication is to measure the output of education services, the focus will be on the third component, i.e. measuring the educational contribution, independently of the two first components. The first two components are supposed to be constant.

The educational outcome for individuals is their education status, i.e. their level of knowledge and skills.

Class size (pupil / teacher ratios) There are many factors creating a quality education environment, which maximizes each student's ability to learn. Class size is one of the most discussed factors of quality and a common belief is that small classes give more benefit than larger ones, and there are studies supporting this (Biddle, 2002). The logic behind this quality aspect is that if there are fewer pupils per teacher, then teachers will be able to devote more time and care to each pupil, i.e. it will be much easier for the pupils to get individual attention from the teacher. It is believed that pupils learn best in small environments and with a lot of discussions within the classroom. However, other studies confirm that class size does not have a statistically significant impact on learning (Wetstein and Mora, 2003).

We may measure class size we mean the pupil-teacher ratio, i.e. the number of pupils in a school divided by the number of qualified teachers. However, in Denmark we do not have data for class size yet, and for that reason this quality aspect/indicator will not be included in the calculations of the output of education.

The teacher/ student time The amount of time a pupil spends with the teacher is also an important indicator of quality, how much time is spent by the teachers with each pupil, how much feedback does pupils get? Feedback is a form of input to the pupils' work from the teacher or supervisors. Receiving constructive feedback gives pupils a clearer idea of how well they are doing in their studies and how they could improve and get some useful advice. Feedback can improve results and strengthen the level of knowledge, since each source of feedback can provide a unique perspective that should be taken into

consideration. Thus, it is essential for the quality of education that the teacher has enough time to give feedback, for instance, on written tasks.

<i>Teacher qualifications</i>	The competence of the teacher in a classroom is supposed to make a huge difference as well, i.e., providing the teacher with the proper curriculum and tools to teach is important and so is the teacher's pedagogical knowledge. The rate of teachers with a relevant education could be applied as a quality indicator.
<i>Projects / team work</i>	The share of time pupils spend on projects and team work could be an indicator of quality, since projects are considered to improve the pupils' skills in terms of being creative, independent, responsible, and thus improve their ability to work in teams, given that collaborative learning is very beneficial, especially if the purpose is to enhance critical thinking and problem-solving skills or to introduce multiple perspectives on an issue.
<i>Academic scores / grades</i>	The academic scores and grades are normally supposed to be a measurement of the level of knowledge and skills. However, all academic scores are subjective. Each teacher has a different subjective method of scoring. Educational attainment, as reflected in examination results, has been the main basis for discussions about quality; but one important question is whether exams can be compared over time; will examinations become easier when the educational institutions know that examination results are regarded as quality indicators? Statistics Denmark does not have access to the examination results, and therefore they will not be included in the quality calculations of education output in this publication.
<i>PISA</i>	The Programme for International Student Assessment (PISA) supplies data for the evaluation of 15-year-olds' competences in reading, math and science. The data covers the period from 2000 to 2006 at an interval of three years. This will be applied as a quality indicator for primary and lower secondary education.
<i>Drop-out rate</i>	A reduction in the share of pupils, who fail to graduate and drop out of school at different levels of education, is regarded as an important quality indicator. Falling drop-out rates are regarded as indications of good education service and high quality. The drop-out rates are available for public primary and lower secondary education

6.3.1 Quality adjustment of Danish educational services

The main difficulty in measuring quality is the availability of data: In this theme publication, we are able to quality-adjust the education outcome with the PISA data and the drop-out rates. Drop-out rates stem from Statistics Denmark's education register. However, the partial data availability will give an incomplete picture of the education output. The data only covers the public primary and lower secondary education.

Weight An important issue is to combine those two quality indicators and weight them by relative importance. In this publication, we have chosen that the two indicators together a weight that is half of the full quality dimension, i.e. 50 per cent of the quality will be covered and the other 50 per cent may be due to other unobserved factors. The drop-out rates are given the weight 20 per cent while the weight given to PISA results is 30 per cent (50 per cent of total).

The quality adjusted output-based price indices for education are calculated according to equation 3.12 :

$$P_{t,t+1}^B = \frac{\sum_i P_{t+1} * M_{t+1} * F(q_{t+1})}{\sum_i P_t * M_{t+1} * F(q_t)}$$

where F is of function of quality and quality is composed of different indicators, which are selected and weighted according to their importance (subjective assessment). The quality adjusted output-based price index for period 2005 to 2006 can be calculated as:

$$P_{2005,2006}^q = 1.029 * 0.997 = 1.026$$

The first part of this equation is the cost index calculated in section 6.2 (quantity) and the second part is the quality index, calculated by the same method as in the example in chapter 4.3.

Quality adjustment of primary and lower secondary education

Output-based price indices *with* and *without* quality adjustment for the primary and lower secondary education are given in table 6.4. The quality adjusted growth rate is lower than the index without quality adjustment, but the differences between the two indices are very small. The lower price indices *with* quality adjustment indicate that the real volume growth will be higher if the production volume is quality adjusted. The quality adjustment is here also assumed to weight half of what will be considered as full quality adjustment, because of lack of data on quality. Again, we do not believe that it is possible to measure the full quality.

Table 6.4 Comparison of output-based price indices *with* and *without* quality adjustment

	2001	2002	2003	2004	2005	2006
	per cent annual growth					
Growth rate for prim./lower sec. ed.						
Output-based <i>without</i> quality adjustment	4.4	3.7	3.2	2.7	3.3	2.9
Output-based <i>with</i> quality adjustment	4.3	3.6	3.3	2.6	3.1	2.6

Positive contribution from PISA negative contribution from drop-out rates

The PISA results indicate improvements in skills of the Danish students, hence contribute positively to the quality, while the drop-out rates are increasing and contribute negatively to the quality. The increase of the drop-out rates in primary and lower secondary educations is primarily due to an increasing number of refugees and immigrants from third world countries, who have less knowledge of the Danish language combined with a lower educational background. This makes it difficult for them to finalize their education; hence positive contribution from quality adjustment to volume growth is from the PISA results. However, as previously mentioned, the quality adjustment is assumed to cover only half of what is regarded as full quality adjustment. The other half is assumed to cover other unobserved and other factors that cannot be measured.

7. Recreation, culture and religion

This chapter describes the sources used to calculate the output-based price index for the individual non-market production of Recreation, culture and religion.

Recreation and cultural services are very extensive and divided into several areas, the areas that will be treated here are:

- Recreational and sporting services
- Cultural services.

Religion is classified as collective service, and since this publication only treats individual services, the figures for religion would not be showed in this publication.

<i>Recreational and Sporting services</i>	In the case of recreational and sporting services when the number of people receiving services is distributed according to the level of service and services, this is classified as an A method. If the total number of people receiving services is used but not distributed according to level of service, this is classified as a B method. Where there is no quality adjustment, this is also classified as a B method.
<i>Cultural services</i>	It is the same case for cultural services, when the number of people receiving services is distributed according to the level of services, this is classified as an A method. If the total number of people receiving services is used but not distributed according to level of service, this is classified as a B method.

7.1 Non-market production of Recreation and Culture in the National Accounts

Public non-market recreation and culture is mainly produced in the sector 920002, which includes both market and non-market production of

- 920002 Recreation, sports and culture

Sector 920002 Recreation sport and culture includes data for the number of visits at libraries, museums, art galleries, exhibition halls, monuments, historic houses and sites, zoological and botanical gardens, etc. It also includes support of facilities for active sporting pursuit's parks, swimming pools and activities like badminton, tennis, golf courses, football, gymnastics, handball etc. Over 80 per cent of the entire sector is non-market.

920002 Recreation, sport and culture

- The production value in 2007 was DKK 11.5 billion measured in terms of current prices
- Over 80 per cent of the production value is non-market

7.2 Output-based price index for recreation, sports and culture

This chapter describes the sources used to calculate the output-based price index for recreation, sport and cultural services and determines output-based price indices, i.e. the quantity part of the output will be calculated by equation 3.8.

$$P_{t,t+1}^B = \frac{\sum_i P_{t+1} * M_{t+1}}{\sum_i P_t * M_{t+1}}$$

The accounts database for public accounts provides the source data for calculating the non-market production value in the national accounts. Since this data is aggregated and needs to be distributed in more detail, Table 7.1 shows an extract from DIOR regarding the services classified as Recreation, culture and religion according to COFOG.

The following three COFOG groups are included in the non-market product number for Recreation, culture and religion i.e. in practice, this division means that individual indices are calculated for:

- 0810 Recreational and sporting services
- 0820 Cultural services

Table 7.1 Non-market production of Recreation, culture and religion. 2007

COFOG		DKK mill.	per cent share
0810	Recreational and sporting services	5 829	29
0820	Cultural services	7 335	36
0830	Broadcasting and publishing services	29	0
0840	Religious and other community services	6 125	30
1050	R&D recreation, culture and religion	286	1
1060	Recreation, culture and religion n.e.c	798	4
0800	Total Recreation, culture and religion	20 402	100

7.2.1 Price index for Recreation, sports and culture

In order to calculate the volume growth for Sector 920002 according to an output-based method, we need some indicators for activity level as well as unit prices. However, it is not yet possible to find the actual activity level and representative key fees for different types of sporting activities that take part in the consumption of COFOG 0810. The total costs for Sector 920002 Recreation, sports and cultural services, are given in the internal database. The activity level or number of individuals who receive those services is not registered directly, thus Statistics Denmark does not have any precise data for the number of individual memberships, sport clubs or any recreational activities. For that reason the level of activity compiled by the share of population who is a member of a sport club, is based on a survey conducted in 2004. The survey sample is based on 1,830 adults (aged 15 or older) and nearly 700 children (from age 7-15)⁸.

⁸ StatBank Denmark.

Table 7.1 shows the annual price increase for recreation, sport and culture. The price is a cost weighted index for different activities in sector 920002 Recreation, sports and culture. There is no clear tendency in the price index; it fluctuates greatly from year to year and the highest fluctuation took place between 2004 and 2005, where it increased from minus 0.6 per cent to 6.3 per cent.

Table 7.1 Price increase for recreation, sport and culture

	2001	2002	2003	2004	2005	2006	2007	2008
	per cent annual growth							
Price increase for recreation, sport and culture	4.9	3.2	3.0	-0.6	6.3	2.7	-0.3	2.6

Generally, there were problems with systematic indicators for the activity level and indicators applied here are uncertain, i.e. collections of more systematic indicators are needed in order to compile a more accurate outcome for Sector 920002.

8. National accounts in the context of output-based price indices

This chapter will show the effects of the output-based method in the National Accounts. It performs a calculation from the national accounts using constant prices. Thus the existing national accounts figures are recalculated using the new, output-based price index, calculated in chapters 4-7. In other words, for non-market public individual services, the existing input-based calculation is replaced by an output-based calculation to see the effects of the new method.

As described in chapter 3, a single price index is not used to calculate the production values for constant prices, but instead the total cost components for constant prices. This chapter, therefore, deduces the implicit price index for existing calculations as the relationship between the individual product production values at annual and constant prices. This price index can then be compared with the output-based price index.

In this chapter only the effects of output-based method *without* quality adjustment will be analysed, i.e. the results from the output-based method *with* quality adjustment will not be analysed in the general context, because only a small part of the production is still quality adjusted.

8.1 Health

As demonstrated in chapter 4, four different price indices were calculated according to the output-based method for constant price calculation from non-market health services. The price index for residential and day care places for the elderly are included in the results for social service in the next section, since the sector 853209 also contains social services for the elderly and adults. Therefore, this section will analyse the effects of the following two indices:

- Price index for hospitals
- Price index for public dental services

These indices are used in this chapter for the new national accounts calculations for health services.

For the sake of clarity, table 8.1 provides an overview of the development of the current and new price indices from 2001 to 2008.

<i>Input-based deflators identical in the preliminary years</i>	From the table, we can see that the current price indices are all identical for 2008. This is because the national accounts calculations for that year have not yet been finalised. Since the calculations are not final, detailed product balances will not be presented and detailed deflation will not be applied. In 2008 the same deflator was used for all non-market services, which is the reason why the price indices are identical. The Danish national accounts are finalised three years after the end of a calendar year.
<i>General hospitals</i>	In the case of hospitals, this comparison shows that the input-based price index measured a higher price growth than the output-based price index did in all years, except for 2003. Figure 8.1 shows that output-based prices of hospital services increased less rapidly than input-based prices and this indicates that real growth of medical services has been understated.
<i>Public dental services</i>	A similar picture emerges in the case of the price index for public dental services; the input-based index grow faster in 6 out of 8 periods.

Table 8.1 Comparison of input- and output-based price changes for health care

Growth rate for:	2001	2002	2003	2004	2005	2006	2007	2008
per cent annual growth								
General hospitals								
Input-based national accounts ...	3.3	3.7	1.5	2.8	2.1	1.6	2.8	3.8
Output-based	0.2	-0.4	1.9	-1.6	1.7	-2.2	2.2	1.3
Public dental services								
Input-based national accounts ...	5.0	3.0	0.7	3.0	2.2	2.2	4.0	3.8
Output-based	-0.3	5.5	0.4	0.9	-1.5	4.0	1.3	-1.5

Based on the price indices for health services, it is possible to conclude that the output-based price index demonstrates more uneven price growth than is the case with the input-based price index, and the output-based price index indicates higher real growth rates of medical care services.

Figure 8.1 Input- and output-based price indices in price for general hospitals

NB: National accounts 2008 are not final.

8.1.1 Calculation of production values

Based on the product balances current prices and the output-based price index, it is possible to perform an alternative national accounts calculation, which clarifies the impact of switching from input to output deflation. Using formula 3.9, it is possible to calculate the product balances for the prices of the previous year. Chained values are then calculated, starting with 2000 prices and based on formulas 3.10 and 3.11. Table 8.2 shows the results of these calculations and a comparison with existing calculations.

Higher production value for hospitals

The calculation for 851100 Hospitals shows that the output-based calculation has a production value that is higher than the input-based value in all periods. Similarly, the annual real growth rate is higher in all periods, except in 2003 where the input-based calculation indicates stronger growth. The calculations clearly show that if the output-based price index is used, the growth in prices would be more moderate, and thus the input-based method understates the real growth rate.

*More moderate change
for doctors, dentists
and veterinarians*

In the case of 851209 Doctors, dentists, veterinarians, the changes are much smaller than for 851100 Hospitals. This is due to two factors: more stable price indices – particularly over the period as a whole – and especially the fact that the non-market services constitute about a quarter of the total production value of the sector. This means that more than three quarters of the calculation is by definition unchanged.

Table 8.2 Input- and output-based production value calculations

	2000	2001	2002	2003	2004	2005	2006*	2007	2008

8.1.2 Productivity for health care

Statistics Denmark does not publish productivity calculations for the non-market economy.⁹ This is because the production value in the non-market economy is calculated on the basis of costs; cf. also chapters 2 and 3. In this publication, productivity is defined as output per hours worked.

The output-based method allows us to calculate productivity figures for the non-market economy. Figure 8.2 shows the evolution of productivity in health care services. Overall, productivity growth is considerably faster with the output-based method; over the period, productivity growth is 2.5 percentage point higher on average. Productivity growth compiled in accordance with the output-based method is positive in five out of seven periods, while productivity compiled after input-based method is only positive in one period. The data for 2008 was not final and the figures for disaggregated levels do not look accurate, and consequently they are not shown here.

⁹ See, e.g. the feature publication: Produktivitetsudviklingen i Danmark 1966 til 2003 (Productivity Growth in Denmark 1966-2003) produced by Statistics Denmark Statistik for the detailed description of Statistics Denmark's calculations.

Figure 8.2 Annual growth rates of productivity for health care

8.2 Social protection

This section will show the effects of the output-based method on calculations of output of social protection services in the Danish National Accounts. The part of Social institutions for adults that is related to residential and day care places for the elderly, i.e. the part concerning health care is also included in the results for sector 853209 Social institutions for adults below. Table 8.3 shows the annual growth rates of the price indices for the two social sectors.

853109
*Social institutions
for children
and young person*

The results for sector 853109 Social institutions for children and young persons show that the output-based indices increase faster than input-based indices, except for 2002 indicating that a real growth rate for this sector has been overstated. The output-based indices also show a more uneven growth than in the case with input-based indices. As mentioned above, there are some inconsistencies in data between 2006 and 2007, because of the local government reform. So, there is a data break in social protection services. Hence, we have chosen not to show the results for 2007 and 2008.

853209
*Social institutions
for adults*

For the sector 853209, Social institutions for adults a weighted price index is calculated. This includes both the part of the sector 853209 that is related to health care services and the part that is related to social protection services. Here is no clear tendency for the output-based price index to grow faster than the input-based price index.

Table 8.3 Annual growth rates of input- and output-based price indices for social protection

Price increase for:	2001	2002	2003	2004	2005	2006
per cent annual growth						
Social institutions for children and young person						
Input-based national accounts	3.7	3.0	2.9	3.2	2.2	2.7
Output-based	6.6	2.5	2.9	6.9	2.3	3.2
Social institutions for adults						
Input-based national accounts	3.5	3.2	2.4	3.1	2.3	2.1
Output-based	2.2	4.3	2.6	3.1	2.5	0.8

8.2.1 Calculation of production values

As in the case of health care services using formula 3.9, it is possible to calculate the product balances for the prices of the previous year. Subsequently, the chained values are calculated, starting with 2000 prices based on formulas 3.10 and 3.11. Table 8.4 shows the results of these calculations and a comparison with existing calculations for the social protection services.

*Lower production value
for sector 853109*

Table 8.4 shows the production value of 853109 Social Institutions for children and young persons based on current input-based national accounts and output-based price indices, respectively. Results show that the output-based calculation has a production value that is lower than the input-based calculations in all periods, i.e. if the output-based indices were used the production value will be lower.

*853209
Social institutions
for adults*

In the case of 853209 Social institutions for adults, the situation is almost the same, output-based method generates lower production values in four periods and higher values in only two periods.

Table 8.4

Input- and output-based production value calculations for social protection

	2000	2001	2002	2003	2004	2005	2006

Difference		- 412	- 764	- 888	- 2 220	- 2 362	- 3 958

8.2.2 Productivity for social protection

Figure 8.3 demonstrates the annual productivity growth for the social protection services. The chart illustrates that the productivity growth is mainly negative, but the output-based method less negative growth. Over the period, productivity fell by 0.3 per cent on average when it is compiled in accordance with the output method – it fell by 2.0 per cent when the input method is applied.

Figure 8.3 Annual growth rates of productivity for social protection

8.3 Education

For use in constant price calculations from non-market educational services, four different price indices were calculated according to the output-based method. These are:

- Price index for primary and lower secondary education
- Price index for post-secondary education
- Price index for tertiary education
- Price index for adult education

In this chapter, these indices are used to perform alternative national accounts calculations for educational services. Again, we have produced a table providing an overview of the current and new price indices; cf. table 8.6.

Input-based deflators identical in the preliminary years

The four input-based price indices are all identical for 2008. This is because the national accounts calculations for that year have still not been finalised. Since the calculations are not final, detailed product balances will not be presented and detailed deflation will not be performed. The same deflator was used for all non-market services in 2008, because the price indices are identical. The Danish national accounts are only finalised three years after the end of a calendar year.

Table 8.6 Annual growth rates of input- and output-based price indices for education

	2001	2002	2003	2004	2005	2006	2007	2008
	per cent annual growth							
Primary and lower secondary education								
Input-based national accounts	3.5	2.9	2.8	3.0	2.2	1.5	2.6	3.8
Output-based	4.4	3.7	3.2	2.7	3.3	2.9	0.9	3.8
Post-secondary education								
Input-based national accounts	3.5	3.0	2.8	3.0	2.2	2.1	3.8	3.8
Output-based	4.0	2.4	5.1	-1.2	4.6	0.5	-0.4	1.5
Tertiary education								
Input-based national accounts	3.5	2.8	3.3	3.0	2.2	2.2	1.6	3.8
Output-based	1.8	0.6	4.4	-0.5	0.8	-0.4	1.7	1.5
Adult education								
Input-based national accounts	3.4	2.6	2.7	3.0	2.2	2.4	2.5	3.8
Output-based	2.9	1.8	6.5	-8.8	-0.7	-0.7	0.5	1.5

Primary and lower secondary education

In the case of primary and lower secondary education, this comparison shows that the input-based growth rate measured a lower price change than the output-based growth rate did in all years, except for 2004 and 2007. All else being equal, this implies that if the output-based growth rate is used in national accounts calculations, the volume growth will be smaller.

Post-secondary education

In the case of post-secondary education, the relationship between the two price indices shows no clear trend. From 2006 and onwards the input-based index grows faster than the output-based one.

Tertiary education

In the case of tertiary education, the input-based growth rate measured a higher price growth than the output-based growth rate did in all years, except for 2003 and 2007. However, the unit prices for research based tertiary education (university education) increased as a result of a "taximeter reform" implemented by the Ministry of Science, Technology and Innovation. All else being equal, this implies that if the output-based growth rate is used, the volume growth will be greater.

Adult education

The output-based growth rate for adult education shows the greatest variation. A relatively substantial price increase in 2003 was negated in 2004 by an even greater

price drop. 2003 is the only year in which this index measured a stronger price growth than that measured by the input-based method. The 2004 drop in the output growth rate is clearly not reflected in the input-based index, but as stated previously, the index for 2004 is merely a general growth rate for the non-market economy. Against this background, it is difficult to compare these. As with the output-based growth rate for health and social services, the output growth rate for educational services shows a more uneven price growth than is the case with the input calculation.

8.3.1 Calculation of production values

As with the calculation for health care and social protection the new production values, in this context, are calculated using the output-based price index. Using formula 3.9, it is possible to calculate the product balances for the prices of the previous year. Subsequently, the chained values are calculated, starting with 2000 prices based on formulas 3.10 and 3.11. Table 8.7 shows the results of these calculations and a comparison with existing calculations.

Table 8.7 Input- and output-based production value calculations for education

	2000	2001	2002	2003	2004	2005	2006*	2007	2008

Difference		- 133	71	- 971	1 441	1 108	1 541	2 886	4 086

In contrast to health services, where there were relatively substantial fluctuations overall, educational services are more consistent between the two calculations. 2003 is the negative extreme where the output-based production value is almost DKK 1 billion lower than the input-based value for education series in total. 2007 and 2008 are the positive extremes. 803000 Institutes of further education has approx. DKK 2 billion in 2007 and 804002 Adult education, etc. has a production value, which is over DKK 1 billion higher in 2007 than in the output-based calculation. This is primarily balanced by 801000 Primary and lower secondary education, where the production value, over almost the entire period, is more than DKK 1 billion lower than when the output-based method is used. In 2008, output-based method produce approx. DKK 4 billion higher production value; sector 803000 Institutes of further education shows a difference about DKK 2.5 billion, where sector 804002 Adult

education etc. shows nearly DKK 1.5 billion, while sector 801000 Primary and lower secondary education exhibits about DKK 1 billion lower production value, when the output-based method is applied. Sector 802000 contributes positively from 2006 and in 2008 the production value compiled by the output method generates DKK 1.3 billion higher production value.

Sector-specific production values

The noticeable drop in production value for 801000 Primary and lower secondary education is not surprising, since the output-based price index grew faster than the input-based index in six of the eight periods. As expected, the production value for 802000 Post-secondary and vocational education varies between exceeding and undercutting the existing calculation. This is due to the measured price growth, which varies in strength. The price index for 803000 Institutes of further education shows the clearest indication of a lower price growth, which is also reflected in the size of the production value. The output-based calculation produces a higher production value in all periods and, except for 2003, the growth rate is also higher in all periods. The price index for adult education showed both the highest increase and the biggest drop. This is also reflected clearly in the calculation of the production value, where the output-based calculation in 2003 is less than the existing one due to the substantial price growth between 2002 and 2003. In 2004, this is replaced by a noticeably higher production value due to an observed price drop of around 9 per cent.

8.3.2 Productivity for education

The growth of productivity for education is demonstrated in figure 8.4. The graph does not show any clear trend in the productivity movements; the productivity growth is positive in four out of seven periods for both methods. On average, the productivity increases by 0.6 per cent per year when it is compiled in accordance with the output method and 0.8 per cent when the input method is applied.

Figure 8.4 Annual growth rates of productivity for education

8.4 Recreation, sport and culture

This section will show the effects of the output-based method on calculations of output of recreation, sport and cultural services in the Danish National Accounts. Table 8.9 shows the development of the price indices for these sectors and it seems that there is no clear trend in the movement of price indices, but the input-based indices seem to be more consistent over time, regardless of 2007 where the data, overall, is not consistent.

Table 8.9 Annual growth rates of input- and output-based price indices for recreation, sport and culture

Growth rate for:	2001	2002	2003	2004	2005	2006	2007	2008
per cent annual growth								
Recreation, sport and culture								
Input-based national accounts . . .	3.5	3.2	2.3	3.1	2.3	2.1	9.6	3.8
Output-based	4.9	3.2	3.0	-0.6	6.3	2.7	-0.3	2.6

8.4.1 Calculation of production values

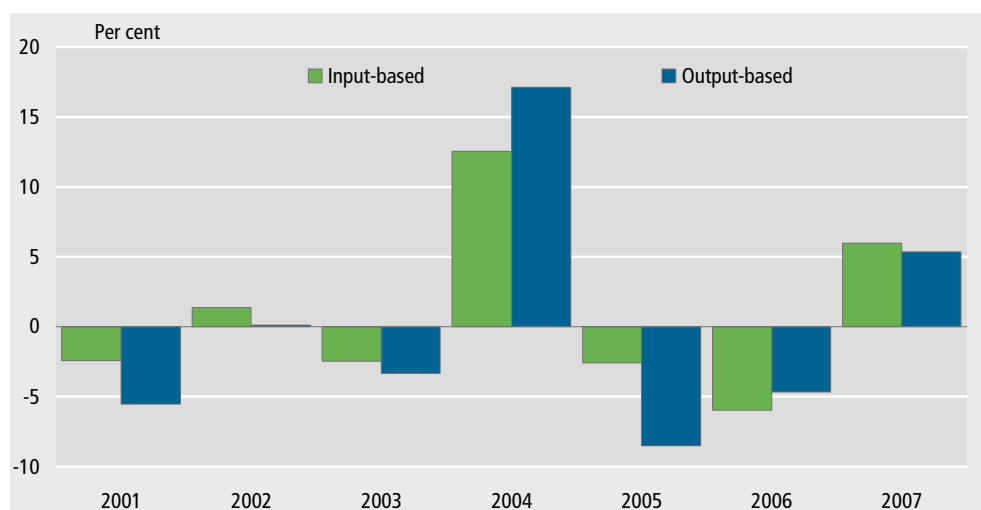

The new production values are calculated in this context using the output-based price index. Table 8.10 shows the results of these calculations and a comparison with existing calculations. The output-based method generates less production value in five out of eight periods, i.e. the current method generally overstates the production value.

Table 8.10 Input- and output-based production value calculations for recreation, sport and culture

	2000	2001	2002	2003	2004	2005	2006*	2007	2008
2000 prices, chained values, DKK mill.

Input-based national accounts . . .	9 081	9 145	9 360	9 304	9 464	9 698	9 798	9 447	9 739
Output-based	9 081	9 033	9 194	9 120	9 564	9 176	9 689	9 598	10 014
Difference	-	- 112	- 166	- 185	99	- 522	- 110	151	275

8.4.2 Productivity for recreation, sport and culture

The productivity evaluation for recreation, sport and culture is demonstrated in figure 8.5. There are no clear trends in the productivity movements; the productivity decreases in four out of seven periods for both methods. On average, the productivity decreases by -0.2 per cent per year when it is compiled in accordance with the output method and 0.8 per cent when the input method is applied.

Figure 8.5 Annual growth rates of productivity for recreation, sports and culture

8.5 The non-market economy in total

This section applies the previous, detailed calculations in a more general context. The consequences of the alternative calculations for non-market economy are placed in the context of some more general concepts in the national accounts.

Price indices for the input- and output-based methods are illustrated below (figure 8.6) and the figure shows that the output-based prices for the whole non-market services grew slower than the input-based prices, which indicates that real growth of the non-market economy has been understated. The differences in price development according to the methods are clearly reflected in volume output of the non-market services (figure 8.7).

Figure 8.8 summarises the differences in terms of production values between the input-based and output-based calculations. The greatest difference is found in 2008, where production is over DKK 15 billion higher. Health services are, by far, the most important factor in this higher production value. Social protection services contribute negatively in all periods and educational services contribute negatively to the differences in the production value in 2001 and 2003. Recreation and culture denote a small part of the total non-market services, and even though it is not very visible in the figure, it indicates that it contributes positively to the production in three out of eight periods.

Figure 8.6 Input- and output-based price growth for the whole non-market economy

NB: National accounts figures for 2008 are not final.

Figure 8.7 Input- and output-based volume growth for non-market services

NB: National accounts figures for 2008 are not final.

Figure 8.9 illustrates the overall difference caused by changing the calculation method in the context of the total non-market production value. It shows that changing the calculation method for non-market public individual services does not significantly affect the level of the non-market economy's total production value. The production value is increased by 4 and 4.5 percent due to the alternative deflation method in 2007 and 2008, respectively.

While the total non-market production value does not seem to change much – cf. figure 8.9 – this is not the case if we focus on growth rates rather than levels. Figure 8.10 shows the growth rates for the two types of calculations for the production value. We can see that the growth rate of non-market production looks slightly different when the output-based calculation is applied. In six out of eight periods, the output-based growth rate increases more than the input-based growth rate. In 2001, 2004, 2006 and 2008, the growth rate increases by 1 percentage point and more, while the increase in 2002 and 2007 is about 0.5 percentage points. In 2003 and 2005, the growth rate is around 0.2 percentage point smaller.

Figure 8.8 Difference in production values distributed according to service type
Chained 2000 values

NB: National accounts figures 2008 are not final.

Figure 8.9 Production value for the overall non-market economy
Chained 2000 values

NB: National accounts figures 2008 are not final.

It is not just the production value that is affected by the change in calculation method. Another crucial parameter, the gross value added, is similarly affected. The gross value added is the production value minus the intermediate consumption in production, i.e. purchase of products. Because only the production value is affected by the change, the gross value added will increase by the same amount as the production value.

Figure 8.10 Real growth rates in production values distributed according to calculation type

NB: National accounts figures for 2008 are not final.

Figure 8.11 shows figures relating to gross value added. From the figures 8.9 and 8.11, we can see that public consumption in production is approx. DKK 100 billion, since the gross value added is approx. DKK 100 billion smaller than the production value. In addition, changing the calculation method seems to have a significant effect on the total non-market value added, the level in 2008 is about 7 per cent higher.

Figure 8.11 Gross value added for the non-market economy overall
Chained 2000 values

NB: National accounts figures for 2008 are not final.

Figure 8.12 shows that the growth rates for gross value added in 2001, 2002, 2004, 2006, 2007 and 2008 with the output-based calculation is greater, while in 2003 and 2005 the growth rate is more negative with the output-based method. In the six years in which the growth rates are now higher, increases of more than 2 percentage point are observed, while the drops in 2003 and 2005 are 0.5 and 0.3 percentage point, respectively.

Figure 8.12 Real growth rates in gross value added distributed according to calculation type

NB: National accounts figures for 2008 are not final.

Productivity As mentioned above, Statistics Denmark does not publish productivity calculations for the non-market economy.

The output-based method allows us to calculate productivity figures for the non-market economy. Unfortunately, the output-based method is not used by all of the non-market economy, but only in relation to individual public services, which make up 73 per cent of the total non-market production.

Figure 8.13 shows the productivity growth for the entire non-market economy. A clear trend according to this chart is that the productivity compiled according to the output-based method grows faster, if the productivity is growing and more negative in periods in which productivity is declining. Overall, productivity is slightly higher with the output-based method; on average over the period, productivity is nearly 1 percentage point higher here.

Figure 8.13 Growth in non-market-related outcome per hours worked distributed according to calculation type

NB: National accounts figures for 2008 are not final. For interpretation of current data, see fact box: Facts about non-market-related finance and work productivity.

8.6 The economy as a whole

This section provides an overview of how the alternative deflation method affects a range of key figures for the overall economy. Figure 8.14 shows the growth rate for gross national product, GDP, according to the input-based calculations, and how individual public services changes the growth rate GDP if they are output-deflated.

Figure 8.14 Annual growth rate of gross national product distributed according to calculation type

NB: National accounts figures for 2008 are not final.

From the chart, we can see that the alternative deflation method affects the GDP growth. The greatest difference in the results is found between the two methods in 2004. While the official growth rate is 2.3 per cent, it is calculated at 2.7 per cent when the output-deflated figures are used. In 2001 and 2006, the growth rates were 0.3 percentage point higher, when the output-based method is applied. In 2002, 2003, 2005 and 2007 the difference between the two methods is between 0 and 0.2 percentage point. In 2008 both growth rates are negative, but the output-based method generates 0.3 percentage point higher growth than the input-based method.

Figure 8.15 Growth in output per hours worked distributed according to calculation type

NB: National accounts figures for 2008 are not final. For interpretation of current data, see fact box: Facts about non-market-related finance and productivity.

Figure 8.15 shows changes in productivity as published by Statistics Denmark along with calculations using the output-deflated figures. The results show that if the alternative figures are used, this will have an overall positive effect on productivity

growth. The well-known picture, in which there is a positive effect in years of positive productivity growth (2002, 2004 and 2006) and less negative effect in years of negative productivity growth (2001, 2007 and 2008) also applies here. The most noticeable difference occurs in 2004, 2006 and 2008 where the alternative calculation produces estimates of productivity growth that are 0.5, 0.4 and 0.2 percentage point higher than the official calculations.

*Output-deflation
contributes higher
productivity*

For the period as a whole, the average growth rate of productivity is 0.4 per cent annually, while the alternative calculations produce an average annual growth rate of 0.5 per cent. These calculations demonstrate that the average productivity growth rate for the period 2000-2006 is 0.1 percentage point higher if the alternative calculations are applied. This difference initially appears relatively modest, but for users of productivity calculations it is substantial. The huge productivity decrease in 2008 is the main reason that the average productivity is low.

One of the most important causes of rising productivity is investment in information and communications technology. Between 2000 and 2003, these investments contributed an average productivity increase of 0.6 per cent, according to Statistics Denmark's productivity calculations.

9. Concluding remarks

Data quality and characteristic for output-based deflators

This publication calculates Danish output-based deflators within the framework of the EU guidelines. The calculations are a continuation and extension of the first two reports on this area, published in 2007 and in 2009. The publication shows, how the output-based method can be implemented for the non-market public services in line with the EU guidelines for calculation of national accounts at constant prices.

In general, the data quality has been high, which is crucial in order to achieve reliable results. The price indices have primarily demonstrated stable results, which is promising for future work of the method. It can be concluded that the results of the output-based method are promising for health care. For social protection, educational services and recreation, sport and culture the data is of international standards, but our assessment is that it could be improved. Especially, the quality of activity data for social protection and recreation, sport and culture could be improved.

Based on the results achieved, it is possible to conclude that calculations covering the whole non-market economy and meeting the international guidelines for calculation of national accounts at constant prices already exist. What makes the current calculations suitable are:

- Almost identical sources for the entire period, which ensures continuity in the calculations
- Data complies with international guidelines
- Calculations are based on data that is also expected to be available in the future

These calculations meet an important criterion for the Danish national accounts, i.e. that data should be of consistent quality. Comparisons over time are worthless, unless data is calculated using the same criteria. The Danish national accounts have a long tradition of ensuring that data is comparable over time. However, it is clear that, since these calculations can only be implemented retrospectively as far as back 2000, a certain amount of continuity is lost, especially as a result of the reform in local governments. Rather than covering a longer period with data of inconsistent quality, which in any case makes comparisons over time more difficult, we will instead focus on ensuring data of a consistently high quality from 2000 and into the future.

Effects of the output-based method

The output-based method generates higher volume growth than the input-based method, i.e. the input-based method understates the volume of government output.

Volume growth for health care services calculated after the output-based method increase more than the input-based method, while social services generates lower growth rates, when output-based deflators are applied. This indicates that the volume growth for social protection in the current National Accounts is overvalued. Generally, educational services grow faster when output-based method is applied. Recreation, sport and culture have minor effects on the main results, since it makes up a very small part of the whole non-market sector.

Quality adjustment of non-market services

The quality issue is an essential part of the output-based method. The first attempts to pin down the difficult area of quality adjustment into operational concepts have been made. Data has been selected and used in several areas. Examples are made with experimental calculations, where it is shown how different quality indicators could enter into the calculations of price indices for General Government services. It is clear that such calculations rely heavily on assumptions on how these effects will influence output. The investigation of this area will continue in the coming year, both regarding the selection of quality-indicators and the way they should enter the calculations of price indices.
